

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

- + *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.
- + *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.
- + *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.
- + *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at <http://books.google.com/>

ON THE SPECIAL FUNCTION OF THE SKIN.*

By R. WILLIS, M.D.

(For the London Medical Gazette.)

THE end for which the cutaneous exhalation exists has been avowed by the first authorities of the age in animal physics and chemistry, not to be understood. "The quantity of solid matter," says Berzelius (*Chimie*, trad. par Esslinger, tom. vii. p. 330), "which escapes from the body by this channel is extremely small, and all its constituents are besides encountered in the urine; the elimination of this matter cannot, therefore, be viewed as the principal function of the skin. Water is, in fact, the chief article thrown off by the skin; and, in speaking of the animal heat, it has been said that the perspiration serves to regulate or depress the temperature of the body when it has been raised by violent exercise or any excessive heat of the surrounding air. But the intimate connexion that subsists between the function of the skin and the bodily health proclaims it to have been instituted for yet another purpose, the nature of which is unknown us."

This statement of the distinguished Swedish chemist is repeated, almost in the same words, by Professor Müller. He says briefly, (*Physiology*, English version, p. 580): "The object of the cutaneous exhalation is not elucidated by its analysis; for the matters met with in it are also constituents of the urine;" and it might have been added, of the organic fluids generally.

My views and inquiries lead me to conclude that the business of the skin is to eliminate water only, that the saline and gaseous ingredients of its secretion are

entirely adventitious. Water, however, unlike the other excretions, is not only not deleterious to the economy, but is indispensable in every one of its operations, and it has, besides, its most obvious, and apparently needful outlet by the kidney, as the vehicle of the urea and the generally little soluble salts of the urine. Wherefore, then, a system charged with the business of throwing off water? The answer always given to this question is that upon which Berzelius is seen condescending particularly; although, by the limitation in the middle of the paragraph quoted, and the concluding observation, with evident misgivings of its sufficiency. The object of the cutaneous exhalation, it is said, is to regulate or reduce the temperature of the body.

There are, however, many considerations which should, I conceive, incline us to regard this particular duty as much more restricted than it is generally believed to be; and, indeed, in the uniformity with which the more perfect animals come into the world ready clothed, and with which man contrives to clothe himself over four-fifths of the earth's surface—the end and influence of the clothing, in every instance, being to prevent the consequences of exposure of the naked skin to the air—we have a sure indication that the animal body has but a limited capacity to engender heat. Nay, is there not even something like an absurdity involved in the idea of a particular system existing for the purpose of dissipating heat,—heat which is the indispensable agent, if it be not, perhaps, the immediate cause of every manifestation of vitality, and which it is one principal business of all the efforts of man over so large a portion of the earth's surface to economise and maintain? To say that the cutaneous exhalation exists for the purpose of cooling the body, is surely to mistake an effect for a cause, to give preference to a minor over a major consequence: heat is lost, indeed, to a great extent from the surface of the living body; but the loss here is

* Read before the Royal Society, March 2d, 1843. Communicated by John Bostock, M.D., F.R.S.

not, cannot be, the end; it is but a means to an end; and this, the researches of the most distinguished physiologists, rightly interpreted, concur in showing to be the dissipation, in the form of vapour, of a certain portion of the watery element of the blood.

The belief, now general, in the great refrigerating power, and, by an extension of the idea, in the refrigerating office of the skin, is grounded on the experiments of our early English inquirers into the subject of animal heat—Fordyce, Blagden, Solander, and Banks. To take the interpretation that is always given of their experiments—and indeed it is the conclusion which they sanction—we should infer that a human being or an animal might remain for almost an unlimited length of time in a chamber heated to twice the temperature of its body, without detriment to its health, and without the acquisition of a single degree of heat. But the experiments of Crawford, and the more recent researches of Messrs. Delaroché and Berger (*Theses de Paris*, 1806, No. 11: *Experiences sur les effets qu'une forte chaleur produit sur l'économie animale*), which are frequently quoted as favouring the same idea, are without a single exception directly opposed to it. Messrs. Delaroché and Berger observed that the health of the animals which were the subjects of their experiments in the hot chamber, was so seriously affected, that few of them withstood exposure in it for an hour without being reduced to extremity, and that when removed either in a dying state or at the moment of their death, their internal temperature was from 11.5° to 15.75° Fahr. higher than it had been on their entrance. Nor was the case different in regard to man; although, from the subjects of observation here not being shut up in the stove till they died, the rise in temperature noted was of course less remarkable. To discover that it was both signal enough and rapid enough, however, the 37th experiment, of which M. Delaroché was himself the subject, may be referred to. On entering the heated chamber M. Delaroché's internal temperature was $29\frac{1}{2}$ Reaum.; on quitting it after no longer a stay than eight minutes, his internal temperature indicated $33\frac{1}{2}$ Reaum. In this very short space of time, therefore, the temperature of the internal parts of M. Delaroché's body had actually gained 4° Reaum., or 9° Fahrenheit.

In a memoir* published several years subsequently to his inaugural dissertation, M. Delaroché himself refers to the misinterpretation of his experiments, and the neglect of the true conclusions to which they lead. He says, in express terms (l. c. p. 291): "J'ai vu constamment que la température des

animaux exposés à une chaleur de plus de 35° ou 40° C. s'élevait d'une manière très marquée; que cette élévation de température allait jusque à 6° ou 7° C.; et je me suis assuré que lorsque la chaleur extérieure est très considérable, cet accroissement de température n'a d'autre borne que la mort de l'animal, qui en est la suite nécessaire." "La faculté de produire du froid," he continues, "est beaucoup plus restreinte qu'on ne le croit ordinairement."

These experiments of Delaroché and Berger, then, prove beyond all question, that the animal body has no power of resisting temperatures of the surrounding medium in any considerable degree higher than itself. Nor does this observation apply only to the excessive temperatures, such as 140° and 190° F. which were used in the experiments of Delaroché and Berger with the dry air stove; it applies equally to atmospheres of much inferior degrees of heat. Dr. Davy, for instance, ascertained that the internal temperature of the companions of his voyage from England to Ceylon, rose gradually as warmer latitudes were gained, and, arrived at their destination, that it was from 2.7° to 3.6° F. higher than it had been in this country. He had already ascertained that the temperature of the sheep was from 1° to 2° , and even 3° F. higher in summer than in winter; and Dr. Edwards subsequently discovered that the temperature of the common sparrow rose and fell with the season. In the month of February the mean temperature of the house-sparrow was found to be 105° F.; in April it was 108° , and in July 111° F. There can be no question of this law being quite general. Man in especial is fashioned in harmony with the varying circumstances in which he is placed as the native or the visitant of every point upon the surface of the earth; and if he have the wonderful attribute of preserving his temperature nearly at the same degree of the thermometer under the equator, and in the icy regions bordering upon the poles, this is certainly in virtue of something else than the greater or less activity of the exhaling function of his skin. The process by which heat is evolved in the animal body, as maintained by the immortal Black in the middle of the last century, is now recognized not to be different, in fact, from that by which it is generated in our stoves and furnaces: in these with the freest access of air and abundance of fuel there is a great evolution of heat; feebly blown, and scantily fed with combustible matter, there is little heat produced. In like manner the quantity of caloric evolved in the animal body is inseparably connected with the energy of the respiratory process, and the kind and quantity of the food that is consumed, and matters are so adjusted that the degree in reference to man and the larger mammalia is

* Sur la cause de refroidissement qu'on observe chez les animaux exposés à une forte chaleur. in *Journal de Physique*, tom. 71, p. 289, et sequent.

uniformly hard upon 98° Fahr. In tropical countries man lives and thrives on a few ounces of vegetable aliment in the course of the day, and here he breathes short, and consumes comparatively little oxygen; in the frozen regions of the extreme north and south, on the contrary, where he takes deep draughts of an air condensed by the cold according to its degree, and consumes a large quantity of oxygen, he must have several pounds of animal food, the fatter the better, in the course of the twenty-four hours, and, in addition, be thickly clad in wool and fur, to be maintained in vigour.*

It is therefore altogether impossible to fix upon any sum that should express the capacity of the human or animal body to produce heat; this varies with every parallel of latitude, with every degree of temperature in the atmosphere inhaled, with the state of repletion and of fasting, of exertion and of repose, &c. &c. Unprotected by clothing, at rest, and feeding upon roots and fruits, the power to maintain a temperature of about 98° F. is probably in relation with an external temperature of from 80° to 90° F.: but shrouded in fur, and well supplied with food abounding in hydro-carbonaceous matter, the standard is maintained, as we know, upon the shores of the Polar Seas.

The temperature of the human body, however, is no constant quantity; it varies even in the state of health, as has been seen—within narrow limits, indeed, yet it varies; in states of disease it presents much more

decided fluctuations. Any rise above the standard, assuming this to be 98° F. for these latitudes, will be effected, we must presume, from what has already been stated, in one of two ways: 1st, by an accelerated circulation of the blood, accompanied by a corresponding increase in the rate of the respiration; and, 2dly, by the body being so circumstanced that it should lose none of its engendered caloric. And we accordingly find that the circulation and the respiration are alike augmented in force and frequency in those circumstances in which the temperature tends to rise, and does actually rise above the standard, as in acute febrile and inflammatory diseases, and when the native of a cold climate, with his capacious chest and voracious appetite, is suddenly transported to a hot climate. But there are very narrow limits to the rise of temperature under these circumstances: excitement in the animal body is ever speedily followed by exhaustion; if the current of blood be driven more rapidly, the wave sent forth by each stroke of the heart soon becomes smaller; if the breathing be quickened, the volume of air inspired is less; and then the appetite for food having failed, there is no longer any fresh supply of combustible material in the shape of aliment, and the body begins to feed upon itself. In short, it is quite certain that the temperature of the human body, labouring under disease, or otherwise, has never been seen higher than that which is normal and appropriate to many animals.

With regard to the second condition needful to a rise of temperature, hinted at above, that, to wit, of the body losing none of its engendered caloric to the surrounding medium, this is a state of things that exists nowhere permanently on the earth's surface. The mean diurnal temperature of the hottest lands within the tropics does not exceed 84° or 85° F.—fourteen degrees under that which is held the standard of the human body in temperate countries; by so much, consequently, must the body be warmed by its inherent powers, in order to maintain itself at its proper temperature. The heat of the air in intertropical regions, it is true, occasionally mounts to 100° or 106°, and, it has been said, even to 110° F., but this is never for any length of time; and it is certain that no degree of activity in the function of his skin then suffices to enable man to support for a succession of days or weeks such temperatures as these. In countries where the thermometer rises at times to 100° F. or more, the inhabitants have to betake themselves at such seasons to caves and cellars, where the temperature is much lower, and there to remain supine; or, to show themselves abroad, and to use ex-

* Vide, in connexion with this subject, Dr. Crawford's classical work on Animal Heat, where all the discoveries of more recent inquirers will be found, ready made, and only requiring to be taken out of their place to be appropriated and found new and highly interesting; as also the appendix to the narrative of a voyage towards the North Pole by Sir John Ross, and the lately published volume of Dr. Justus Liebig: Animal Chemistry, in connexion with Physiology. The following extract is from Dr. Crawford's second edition, Lond. 1788.—

"It appears, therefore, that the heating and cooling powers in the animal body are adjusted to each other in such a manner as to produce an equal effect; and, consequently, the law by which animals maintain a uniform temperature, notwithstanding the variations in the heat of the surrounding air, is similar to that by which the temperatures of bodies become fixed when they have arrived at the melting or freezing points.

"Hence the power which animals possess of generating heat is, in all cases, proportioned to the demand. It is increased by the winter colds, diminished by the summer heats.

"Among different animals, those are the hottest which breathe the greatest quantity of air in proportion to their bulk; and in the same animal the degree of heat is in some measure proportionable to the quantity of air inhaled in a given time.

"These varieties appear to be the necessary consequences of the general fact that the heat of the breathing animal is derived from the air. For if animal heat depends upon a change which the air undergoes in the lungs, it is evident that, all other circumstances being equal, the greater

undoubtedly risen to a point that was incompatible with the continuance of life; precisely as happened with the animals which were the subjects of Delaroché and Berger's experiments. Under such circumstances, the function generally ascribed to the skin as the refrigerator of the body would certainly come into operation; but what shall be said of a natural function that proves incompetent to its office, that fails to preserve the body in health; or of one that should only come into play under peculiar circumstances, at particular times, and over a very limited portion of the earth's surface? A refrigerating faculty of the skin might, therefore, sometimes be found useful within the tropics; but wherever man feels the necessity of clothing himself, there it would be useless. In temperate and cold climates such a faculty is not only not required, but is even sedulously guarded against. Nevertheless, the office of the skin is indispensable to life in every climate of the globe—at the arctic circle as under the equator.

And here a very important question naturally presents itself: Is the diminution or suppression of the perspiration, sensible and insensible, necessarily and invariably followed by a rise in the temperature of the body? It ought to be so if the views of the cutaneous function generally adopted be well founded.

In febrile and inflammatory diseases it is familiarly known that there is an increase of temperature, and along with this, as is commonly said, a suppression of the cutaneous exhalation. That there is a diminution in the exhaling function of the skin during the hot periods of fevers seems certain; to assert that there is a total suppression is, I believe, an error. I have always seen a polished plate of metal, brought close to the most burning skin, become dim. And then, are there not other circumstances in which the exhaling function of the skin is in abeyance, yet in which the temperature falls below the standard? Yes, there are. In the initiatory cold stage of fever, when the skin is dry and shrivelled, the temperature sinks; and in oedema of the extremities, and in the second and later stages of general anasarca, where the cutaneous perspiration is more completely suppressed, perhaps, than it is in any other disease, the temperature is constantly found to decline. Under no circumstances do we observe so icy a state of surface, and, I believe also, so low a grade of internal temperature, as accompany the dry and parchment-like skin of subcutaneous dropsy. In that curious disease of early infancy called scleroderma, or skin-binding, one of the very remarkable features of the disease is the loss of vital warmth, which begins at an early period of the affection, and in fatal cases—and the great majority of cases are fatal—goes on continually augmenting until

life is extinct, when the internal as well as external parts of the body are often 10°, 15°, 20°, and even 23° F. under the standard. Similar depressions of temperature, internally as well as externally, are well known to follow extensive destructions of the skin by burns and scalds, when its peculiar function is of course annihilated. Now the rise in the temperature generally, which accompanies febrile diseases, when the exhaling function of the skin is certainly diminished, and the fall in the temperature under other circumstances, when the same process is implicated in fully as great a degree, assure us that the increase of temperature in the one case, and its fall in the other, depend on something which is not included in the commonly-admitted theory of the cutaneous function. We have happily the evidence of other positive and most remarkable facts to prove that such is the case.

M. Fourcault had ascertained that an animal whose body was covered with an impervious glaze or varnish, in every instance suffered a notable derangement of health; and, if the application were tolerably complete, that it perished after the lapse of a few hours, or of several days. Whether M. Fourcault noted all the phenomena which precede and accompany the extinction of life under such circumstances does not appear from the notice of his Memoir to the Royal Academy of Sciences of Paris, which has been given to the public (*Comptes Rendus des Seances de l'Academie Royale des Sciences*, &c. tom. ix. p. 44.) The experiments of M. Fourcault have, however, been recently repeated by Messrs. Becquerel and Breschet*, and they observed that the suppression of the cutaneous exhalation was immediately followed, not by a rise, but by a signal fall, in the temperature of the animal, and this not only as regarded the surface, but the deeper internal parts also—a fall that went on increasing every instant from the beginning of the experiment till life was extinct, when the body was found to be but a few degrees Cent. higher in temperature than the surrounding air. Thus, in their first experiment, Messrs. Breschet and Becquerel found that a rabbit, prepared in the manner of M. Fourcault, whose internal temperature at first was 38° Cent., had fallen in half an hour to 32° Cent.; and in an hour to 24°·5 Cent. In their second experiment, another rabbit, very carefully prepared, had fallen, in one hour and a half, from 38° C. to 20° C., no more than three degrees above the temperature of the atmosphere, which, on the occasion, indicated 17° Cent. In one hour and a half more the animal had expired.

To the conclusion that such would be the case I had myself attained from observing the phenomena of disease, and from analogi-

* Vide *Comptes Rendus*, Oct. 18, 1841.

DR. WILLIS ON THE SPECIAL FUNCTION OF THE SKIN.

cal reasoning. I had seen the function of the skin as an essential element in the process of nutrition, and concluded that, were that function arrested, this process would cease, vital manifestation be at an end, and the temperature fall as a matter of course.

The ideas formerly entertained in regard to nutrition and secretion as effected by open-mouthed capillaries are no longer tenable, are no longer maintained: there is no such thing as an open-mouthed capillary vessel; every capillary artery ends in a capillary vein, and nutrition and secretion are accomplished by an elective attraction between the substance of the several tissues and organs and the appropriate matter held in solution in the general nutrient fluid—the blood. But the blood, still contained within its conducting channels, being inefficient as a vivifying fluid, transudation of these channels by the plasma, or prepared nutrient element, is implied; and this is now known and acknowledged to take place abundantly at every point of the body: the spongy texture of the canals in which the blood is contained, particularly when put on the stretch by the injecting force of the heart, permits the freest transudation. But how, or by what means, does the fluid thus incessantly transuded find its way back into the circulation? That it should do so was obviously even as necessary as that it should escape. The answer generally given to the question just asked is this: the exuded fluids return into the veins by heterogeneous attraction or endosmose. And this is true. But the conditions to endosmose, in the sense in which that remarkable phenomenon is usually understood, are the mediate contact of fluids having different densities; and no means have yet been assigned by physiologists for securing a greater degree of density in the returning current than in the outgoing current of the circulating fluid. This means I find in the exhaling function of the skin, the end and import of which I regard as subservient to securing the conditions that are necessary to the return into the venous circulation of the fluids that have been shed from the arteries for the purposes of nutrition and vital endowment.

Reasoning *a priori*, we should have said that the blood returning in the veins to the heart must be more dense than that which is leaving it, by the whole amount of watery fluid abstracted in the course of the peripheral circulation. That which is true of the whole must also be true of the several parts: the venous currents of secreting organs, the products of which are essentially watery, must be more dense than their arterial currents. The blood of the emulgent vein, for example, must be denser than that of the emulgent artery by the entire amount of water, less the saline matter, which is taken

from it in its passage through the kidney. But as the density of healthy urine is no greater than 1·015, 1·020, or 1·025, whilst that of the blood is from 1·010 to 1·060, it is obvious that the degree of densation effected in the portion of which has circulated through the kidney must be very considerable. The blood of the hepatic vein, in like manner, must be more dense than that of the vena porta: the whole quantity of water which is removed from it in its course through the liver forms the bile. So, also, the returning current from every secreting gland, the portion of which is essentially watery, must be more dense than the outgoing current. If the blood which is circulating in the peripheral parts of the body must be more dense in its circuit by the quantity of pure water which is taken from it by the extensive system of sudoriferous glands, a quantity which has been ascertained to amount, on an average, to upwards of thirty ounces per diem.

Direct experiment demonstrates that this is the case. Dr. Davy, in one of many series of ingenious researches, which he has instituted in the course of his life, ascertained that the specific gravity of arterial and venous blood, taken at the same moment from the same animal, differed materially in every instance, save where the two fluids were of the same density. Dr. Davy found, farther, there was a corresponding, but still remarkable, difference in the specific gravities of the serum of the two kinds of blood. Taking the mean of the whole of Dr. Davy's experiments, the specific gravity of venous blood turns out to be 1·053; that of arterial blood but 1·050. The specific gravity of the serum of venous blood, again, appeared to mean to be 1·026; that of the serum of arterial blood no more than 1·022*.

* The following table is taken from Dr. Davy's Researches, Anatomical and Physiological, vol. ii. p. 24.

Table shewing the specific gravity of blood, and arterial, of different animals, and of different ages.

Animal.	Age.	Art. bl.	Ven. bl.
Sheep	1 ..	1050	1036
	2 6 years	1057	1038
	3 16 mo.	1049	1051
	4 ..	1047	1050
	5 3 years	1047	1051

	2 ..	1046	1057
	3 ..	1054	1064
	4 ..	1050	1053
	5 ..	1047	1050
Ox	—	1058	1061
Calf	—	1040	1046
Dog	—	1048	1055
Mean	1051	1053

Dr. Herman Nasse, in his admirable work on the blood*, informs us that his researches agree, in almost every particular, with those of Davy. In every one of his trials he found the venous blood of somewhat higher density than the arterial blood, the difference being generally about 3.0 in favour of the former. He, also, on no occasion found the serum of venous blood of lower specific gravity than that of arterial blood; on the contrary it was generally appreciably heavier, the amount in its favour falling between 0.5 and 2.1 in 1000.

Hering† also ascertained that the venous blood of the ox, sheep, and horse, contained less water than the arterial blood. The mean of all his trials gives about 825.6 for the quantity of water contained in 1000 parts of arterial blood, and 812.0 for the quantity contained in 1000 parts of venous blood.

Dr. F. Simon‡, of Berlin, has very recently confirmed these interesting results obtained by Davy, Nasse, Hering, and others, not only in regard to arterial and venous blood at large, but, having extended the sphere of his inquiries, in reference to the arterial and venous, or out-going and in-coming, currents of several particular organs or systems. He always found the arterial or out-going current to contain a larger quantity of water, i. e. to be of greater density, than the venous or returning current, the difference, as might have been predicated, being greatest in reference to those organs where there was the most abundant separation of watery fluid.

In repeating these experiments upon the sheep, I have very regularly found the serum of venous blood of somewhat greater density than that of arterial blood; and even when, through imperfection of apparatus, the difference was extremely slight or inappreciable, on putting quantities of the two kinds of serum into an apparatus for shewing endosmose, I have still seen a current of considerable power established from the arterial to the venous side. This is the process, in fact, which, as carried on between the arteries and the veins of a living creature, constitutes venous absorption, the conditions necessary to which, viz. the higher density of the blood in the veins or returning vessels than in the arteries or efferent vessels, in all the peripheral parts of the body, being mainly due to the influence of the sudoriporous glands. In this way we perceive, at once, how the elimination of so much simple water from the surface of the body becomes so indispensable to health and life as it unquestionably is.

In connection with the important function of the sudoriporous glands, it is interesting to observe that the skin, in health, is especially aroused to activity under circumstances that increase the force and frequency of the heart's contractions: we perspire more copiously as we use more violent exertion. Wherefore is this? We do not observe that any of the other glands or glandular systems are excited to peculiar action under the same circumstances: the salivary glands do not then pour out more saliva than usual; on the contrary they seem to pour out less, so that the mouth becomes clammy and dry. The kidneys do not then elaborate more urine than wont; they seem often rather to eliminate less, &c. &c. The usual explanation given of the diminished activity of the salivary glands and kidneys is anything but satisfactory; the blood, it is said, being circulated in larger quantity to the capillaries of the skin, is therefore sent in less measure to the internal organs. But it is obvious that, as the heart injects a common trunk, which feeds the vessels of every part of the body, if there be more blood passing through the capillary rete of the skin during active exertion, there must, in like manner, be more passing through that of the kidney and of every other element of the body. Wherefore, then, the signal activity of the glandular apparatus of the skin under the circumstances indicated? First, because there is, with the accompanying augmented vigour of respiration and circulation, a more rapid consumption of carbon, and a consequent greater evolution of heat; second, because the function of the glandular apparatus of the skin is essential to secure the return into the venous system of the plasma which, under the influence of the extraordinary injecting force of the heart, is transuding the coats of the capillary arteries in unusual quantity: the returning stream must be inspissated in an unusual degree in order to have the endosmotic current from the areolæ and interstices of the component particles of the body into the veins, of power sufficient to keep the system drained of the fluid that is tending to overwhelm it.

In connection with this part of the subject it is farther not unimportant to observe that the sudoriporous glands are largest and most active in the precise situations where their function is most wanted, and also where it is calculated to prove of the greatest avail—the hands and feet. Insensible in every other part of the body, the perspiration is almost at all times sensible in the palms and soles; it never fails to become so under very slight exertion of any kind. The glandular apparatus of the skin has this peculiarity also, which we observe in none other, unless, indeed, the lymphatic system be regarded as the essential element of an

* Das Blut in mehrfacher Beziehung, Bonn, 1836.

† Physiologie für Thierärzte, Stuttgart, 1832.
‡ Handb. der medicinischen angewandter Chemie, Berlin, 1841-1842.

universally distributed gland, which seems very probable—that it is *not concentrated*, but *diffused*; it is spread over the entire surface of the body; an arrangement which leads us to infer that its function was also needful over the entire periphery; for we very certainly find glandular organs in the neighbourhood of parts where their office or the products of their activity are required.

The value of the power engendered by the difference of density in the out-going and in-coming streams of the circulating fluid, in explaining morbid phenomena of several kinds, will be at once appreciated by the pathologist. It was, indeed, whilst engaged in studying the pathology of those diseases that are accompanied with effusion, and after having satisfied myself of the insufficiency of the generally received theories of their production in many instances, that I was led to look farther, and to discover a powerful and, as I believe, hitherto neglected cause of their origin in whatever interferes with the accomplishment of the conditions that are necessary to secure the normal difference of density between the arterial and venous portions of the circulating fluid. Whatever hinders the blood in the arterial capillaries from losing a portion of its water, will immediately have the effect of inducing effusion,—not primarily, however, as the expression *inducing effusion* would seem to imply, but secondarily—and in consequence of the normal effusion from the arteries not finding its way back, by heterogeneous attraction or endosmose, into the capillaries, the smaller and larger branches, and even the main trunks of the returning channels.

[The appendix to this paper, embracing pathological views from the preceding physiological considerations, in an early number.]

CONTRIBUTIONS TO THE PHYSIOLOGY OF THE HUMAN OVARY.

By CHARLES RITCHIE, M.D. Glasgow.

PART II.

SECTION VI.—*Ovaries in women, five, six, seven, ten, twelve, and thirty-six months after natural delivery, menstruation not having been re-established.*

1. Mrs. J——, aged 40. Mother of a family, the youngest being five months old. Ovaries large. Two or three minute vesicular points, and

vascular macules, on exterior. Interior of both occupied by several vesicles, one or two of which were as large as small dried peas. In one ovary were the fragmentary remains of an opaque cyst, and in the other, a globular-shaped, cartilaginous looking body, of the size of a large hemp-seed, of a bright canary yellow colour, and corrugated irregular surface, surrounded by a well-formed capsular covering, from which it could be easily enucleated, its only observed organic connection being a minute pedicle. The capsule, also, with a little gentle pulling, was raised from the ovary in the form of well-organized membrane, resembling the hull of a garden pea.

2. Mrs. M——, aged 35 years. Mother of five children, youngest being six months old. Appearance of menstruation for part of a day three weeks before death. Surface of ovaries occupied by some old cicatrices but nearly faded, by a few pores impermeable to a bristle, but which gave exit on pressure to a little fluid, also, by some minute vesicular elevations, which, on cutting into gland, were noticed to be portions of Graafian vesicles of about the size of coriander seed, imbedded in the peritoneal coat, with many more of which, filled with opaque fluid, and having thin delicate coats, the thickness of the peritoneal investiture, and the parenchyma of the glands, were studded, without any other appearance.

3. Mrs. L——, aged 30 years. Two children, youngest six months old.

Ovaries remarkably large, and nearly quite smooth, the vestiges of old fissures being scarcely to be perceived. Every part of interior of both glands richly studded with small but highly injected Graafian vesicles, without any trace of a cyst of any kind.

4. Mrs. R——, aged 42 years. Six children, eldest fourteen years, youngest six months. Both ovaries large, plump, fresh-looking, and without a trace of linear scars. Surface studded with minute vesicles; some in the form of dark spots only, not having yet penetrated the peritoneal covering; others protruding by a portion of their circumference through it, and others, again, burst, and exhibiting puncta still exuding fluid. A well-defined white body in each ovary, with another less marked, and numerous turgid osiaces, were the only

5. ———, aged 40. Death from dropsy six months after delivery. Ovaries large, plump, and free from the cicatrices of the menstruating period, but tender at some points as if from the recent lesion of minute vesicles, and having large segments of two white bodies projecting from the peritoneal surface, which in this situation was absorbed. Within the one ovary there were six, and in the other eight white bodies, varying from the bulk of a mustard-seed to that of a large pea, and each constituted of a dense, corrugated, internal hollow membrane, inclosed in a thin but distinct and vascular covering, and this again in a capsular condensation of the ovary.

6. Mrs. ———, mother of ten children, youngest seven months old. Ovaries nearly smooth, but dotted with a number of open pores, and contained internally some Graafian vesicles, and about six little fatty looking and fissured white bodies, but no other cyst.

7. Mrs. R——, aged 37 years. Six children, youngest seven months old.

One ovary. Internal surface perfectly smooth, excepting two points of the diameter each of about a line, which were transparent vesicles, encircled at their bases by delicate opaque margins; also another point exhibiting a yellow elliptical-shaped vesicle of size of a pin-head, and a third which was a capillary-sized solution of the continuity of peritoneum. Internally were numerous small vesicles, one white body of size of a hemp seed, and as white as snow, and several grains of rhubarb-coloured matter.

Other ovary.—Free edge vascular and tender looking, as if from recent rupture of several small vesicles; one of which remained, of a scarlet colour, and with about two-thirds of its circumference external to peritoneal coat. In the structure of the surface of the ovary was a tumid ring of size of a barley-corn, having a central depression and pore, through which a bristle could be introduced into an empty vesicle, with opaque, but otherwise unaltered coats; also, one or two rhubarb-coloured points, and several vesicles, but no white or other body.

8. Mrs. H——, aged 32 years. Had had five children; youngest, which was lactating at mother's death, was ten months old.

One ovary.—Numerous old fissures,

four or five minute transparent vesicles, and two puncta with red delicate areolæ on outer surface, and internally, four miliary sized white bodies, with the rough granular or fissured look, which depends on their state of great contraction on their cavities, and some vesicles.

Other ovary.—A yellow, shining, concretion of the consistence and appearance of candied sugar, and of the size of a pin-head, was imbedded in a superficial cup in the peritoneal coat; no minute vesicles, but one vascular pore was seen; and there were many pale coloured fissures, and at two points there appeared small mamillated tumors protruding from the surface. On laying these open, one was found to be a corrugated hollow body of a solid consistence and shining whiteness, inclosed in a thin capsule, and the other, which was also surrounded by a vascular covering, from which it was turned out with some adherent shreds of its substance, was likewise a corrugated corpus albidum, as large as a marrowfat pea, and contained some yellow fluid in its white shining cavity. There were also observed two other circular white bodies with capsules.

9. Mrs. C——, aged 42. Mother of six children, youngest a year old. Ovaries smooth, with exception of two slight indentations of old standing, corresponding to which internally were white bodies of cartilaginous consistence. Circumference of ovarian parenchyma studded with small vesicles.

10. C—— F——, aged 33. Mother of six children, youngest being three years of age. Had not weaned child, or menstruated.

Right ovary.—One inch seven lines in long, and six lines at broadest part of short diameter, smooth and of a reddish white colour, but viewed with a strong power some faint linear cicatrices were seen on surface, under which were two convoluted, fatty, or gristly, white bodies.

Left ovary.—One inch and three lines in length, and six lines broad. Two small vesicles beginning to present on smooth and white surface, and inner structure of both glands occupied by a number of unruptured Graafian vesicles, having their coats highly injected with blood. No traces of any other bodies.

[To be continued.]

A CASE OF
INVERSION OF THE UTERUS,

With Observations,

By T. HERBERT BARKER, Esq.

Member of the Royal College of Surgeons of England, Fellow of the Royal Medical and Chirurgical Society of London, formerly House Surgeon to the University College Hospital, &c.

(For the Medical Gazette.)

ON January 21st of the present year, Mrs. C. was delivered of her first child after a labour of about six hours' duration. The liquor amnii escaped after the full dilatation of the os uteri. Eight or ten minutes elapsed between the birth of the head and that of the body, and about twenty minutes between the birth of the body and the expulsion of the placenta. The cord was of the average length, and not twisted around any part of the body. The placenta was detached and removed without more than ordinary traction of the cord. A napkin was applied to the external parts, and a bandage around the body, about twenty minutes after which my attention was arrested by a severe pain in the region of the uterus, which lasted about half a minute, and was not immediately followed by any discharge. In about half an hour after the expulsion of the placenta, having prepared an anodyne draught, I was about to leave the house, when I was called to my patient by the nurse, who stated that she was in a fainting-fit. On hastening to the bed-side, I found that she was indeed extremely pallid and exhausted. Ordering the immediate administration of some brandy and water, my attention was instantly directed to the vagina, and I found the napkin saturated with blood, which was flowing from the vagina to a fearful extent. Fearing that she would rapidly sink from the hæmorrhage, I was led, instinctively as it were, to introduce my hand into the vagina, with the view of plugging the cavity, and stopping the profuse flow of blood by pressure immediately upon the patent vessels. Just within the orifice of the vagina my fingers encountered a firm, hard, somewhat globular-shaped body, about the size of a small fœtal head, from the most depending part of which the blood was proceeding. At once regarding it as a case of inversion of the uterus, I

in my hand, and tried by gentle and continued pressure to effect reinversion of the organ, sending for the aid of my skilful and experienced friend, Mr. Hurst. Having now the hæmorrhage under control, my alarm for the safety of the patient somewhat subsided, and I continued my efforts to reduce the uterus, sometimes grasping the tumor, sometimes endeavouring to push it up with the back of the hand, (which latter mode only slightly dimpled the most depending part of the tumor,) but ineffectually, until Mr. Hurst arrived, when I withdrew my hand, to have the opinion of that gentleman. Confirming my diagnosis of the case, we thought it desirable that no time should be lost in endeavouring to replace the inverted organ, which Mr. Hurst accomplished in about a quarter of an hour, by firmly grasping the tumor, at the same time making pressure upwards. Thirty drops of the tincture of opium were administered in brandy and water, and a sheet, several times doubled, was cautiously placed under the hip, in order to elevate the pelvis. The strictest quietude was enjoined, and I narrowly watched my patient for an hour and a half, occasionally examining per vaginam, and above the pubes, to ascertain if the body of the uterus retained its natural position and contracted state. At the end of that time, finding the os uteri, which before had been remarkably lax and flaccid, had pretty firmly contracted, that the body of the uterus was contracted above the pubes, that there was no discharge, and that my patient had thoroughly rallied, I felt at liberty to leave her, and she has since progressed to a favourable recovery, suffering from nothing more than inaction of the bowels. During life she has been affected with prolapsus of the rectum to a considerable extent.

So much of interest belongs to the case briefly related above, that I cannot allow its publication to pass without making a few observations, which, though they may not lay great claim to originality, may yet be serviceable to the junior portion of your readers. The references might have been much more numerous, but have been made from works more immediately within my reach, and will amply serve the purpose for which they are given.

nately of rare occurrence there can be but little doubt. In rather an extensive midwifery-practice during the last few years, a case of the kind had never before presented itself to my notice; and in a much more extensive practice, and through a much longer period, my friend Mr. Hurst had met with but one case, which occurred to an irregular practitioner. In this case the child and placenta had been expelled before the party reached the house, who then proceeded to remove the latter, when he found it accompanied by something unnatural, and looking upon it as a diseased mass, cut it away *sans ceremonie*. The poor woman died, and on making a post-mortem examination Mr. Hurst found the protrusion to have been the completely inverted uterus. Dr. Robert Lee saw one case in 1826 at Odessa, after death had occurred, and adds, "I have not seen one case of inversion of the uterus since, which proves that at the present time the accident rarely occurs in London*."

Causes.—The present case most decidedly confirms the opinion of Dr. Radford, and a few others†, that this displacement of the organ may depend upon other causes than violent traction of the cord during an unusually relaxed condition of the uterus. In this instance there was no inordinate force employed in bringing away the placenta, and the severe pain which followed some time after its removal, with the firm condition of the body of the uterus, would tend to prove that there was an active and contracted, rather than a relaxed state of the organ. To nothing more aptly could the inverted portion of the uterus be compared than to a large caoutchouc hydrocele bottle,—supposing its parietes to be rather thicker and firmer than usual. Although the fundus and body of the organ were firm and contracted, the os and cervix were extremely relaxed: hence the facility with which the former parts were protruded under the irregular contraction of the organ.

There appears to be some discrepancy between many of our obstetric writers on the cause of this inversion, as well as on other points connected with it. Dr. Hopkins states that it

may be brought on, or commenced, "1st by violence used in pulling the funis; 2nd. by withdrawing the hand from the uterus with the placenta before it was perfectly separated; or 3rd, by the shortness of the funis. If the inversion ensued from too great a degree of force in its extension, it may be completed by the action of the uterus; and, if by the shortness of the cord, it may be effected by a small effort in pulling*." Mr. Newnham writes, "the most frequent cause of inversion of the uterus is the imprudent management of the placenta, and rude attempts to hasten its expulsion, by pulling at the cord; but this accident may likewise be occasioned when the patient is encouraged to make vehement voluntary efforts to bear down, at the moment when the fœtus is about to be pushed into the world; it may be produced by the child being suddenly born, while the woman is in an erect position, and consequently the excessive capacity of the pelvis will be a predisposing cause of the disease: and it may arise from carelessness in the management of the delivery, when the funis is either preternaturally short, or is rendered so by its being coiled round other parts of the body. These causes will all operate more powerfully in proportion as the uterus may be in a torpid or atonic state†". According to Dr. Burns, "Inversion in a great majority of instances depends upon the midwife endeavouring to extract the placenta by pulling the cord‡." The same author asserts that it may happen if the child be allowed to be rapidly expelled, if the cord be short or entangled about the child, or from sudden pressure of part of the intestines on the fundus uteri. In the London Practice of Midwifery the only cause assigned is "pulling at the cord," and an ignorant midwife is stated "like most midwives" to have pulled "at the navel-string as she would at a bell-rope§."

Dr. Conquest traces it "almost always to the employment of an immoderate degree of force in withdrawing the placenta, before the uterus has con-

tracted on the mass. It can scarcely happen to a cautious practitioner, who, instead of hastily extracting the placenta, exclusively aims at securing its detachment and expulsion by exciting the uterus to its secondary contractions, and who never permits the mass to slip out of the vagina, without ascertaining by one or two fingers of the left hand, that, as it passes, it does not drag the inverted uterus with it* ; and in two or three other places, treating of the management of the placenta, and of hæmorrhage, he alludes to inversion as if referrible in most cases to mismanagement during a relaxed state of the organ, (see pages 70, 71, 76, and 166.)

"Inversion of the uterus," says Dr. Lee, "is frequently, if not invariably, the consequence of pulling at the umbilical cord, to extract the placenta immediately after the birth of the child, before the uterus has had time to contract, and while the placenta is still adherent†." By Dr. F. H. Ramsbotham it is classed amongst the "Accidents likely to happen on attempts to remove the placenta from the uterus, by pulling at the funis," and he remarks that it "may generally be looked upon as the consequence of improper treatment‡." Dr. Campbell does not hesitate to ascribe it "to mismanagement in the removal of the placenta, and its rare occurrence in the present day, that this duty is now better understood : " further on he adds, "displacement has happened, however, in some instances spontaneously, and the uterus seemed to be impelled per vaginam, with great force and rapidity§."

On the other hand, it may be inferred from the following extract that Dr. Denman did not regard it as solely or so frequently attributable to traction of the cord, as his predecessors and contemporaries. "With respect to the causes of the inversion, it has generally been attributed solely to the force used in pulling by the funis, in order to bring away a retained placenta. But there is reason to believe, that the uterus

has been inverted, when, on account of a hæmorrhage, or some other urgent symptom, the hand has been introduced within its cavity while in a collapsed or wholly uncontracted state, and the placenta being withdrawn before it was perfectly loosened, the fundus of the uterus has unexpectedly followed, and a complete inversion been occasioned. I have also been assured that in some cases there has been a spontaneous inversion; that the accident happened, at least when no force, or none capable of producing the effect, had been used; and then it was imputed to the shortness of the funis, giving the disposition before the birth of the child; or to some untoward action of the uterus. But with this assurance, or explanation, I do not feel quite satisfied, because degrees of force must always be vaguely estimated; though if a disposition to an inversion be first given by the force used in pulling by the funis, it may be completed by the action of the uterus; or if the least possible degree of inversion were given by the shortened funis, it might certainly be completed by a very slight additional force in pulling by the funis, or by the mere weight of the placenta.

Ruysch, whose animadversions on the conduct of midwives are sufficiently severe, especially with respect to the hasty or violent methods of extracting the placenta, to which only he attributes the inversion of the uterus, afterwards acknowledges that the accident may, and did happen in his own practice, when no violence was used. His words are very striking: "*Quamvis hoc malum oriatur nonnunquam obstetricibus minus expertis, funiculum umbilicalem plus quam par est attrahentibus, aliquando tamen ortum ducit a conatibus post partum remanentibus*". In the cases, however, to which Ruysch alludes, it seems probable that there was some preceding partial inversion, and this was completed by the subsequent action of the uterus*. Dr. Waller in his note to this chapter writes, "Some persons have doubted the possibility of a spontaneous inversion of the uterus ever having taken place, and the editor confesses that he himself was formerly one of this number, but a case related to him by his friend Dr. Williams, of Guildford Street, has

§ Introduction to the Study and Practice of Midwifery, by Dr. W. and A. B. Campbell.

... the Principles of Midwifery.

quite convinced him that such an occurrence occasionally takes place" (p. 424). "It has been supposed," writes Dr. Merriman, "that the exploded practice of dragging at the funis, to extract the placenta immediately after the birth of the child, was the principal cause of this misfortune; but I have known the accident happen when the hand of the operator was introduced for the purpose of effecting the separation; and there can be no doubt that a spontaneous inversion has sometimes occurred*."

Dr. Radford has brought together a greater number of facts, and stronger arguments, than any other obstetric author that the writer is aware of, to prove that inversion of the uterus is not so frequently the result of mismanagement as has too generally been considered, and to make good his position that it depends "upon a power inherent in the uterus;" that, in fact, the fundus and body of this organ, "so far from being in a state of collapse or relaxation, are really in a state of unnatural excitement and action," accompanied with a yielding and relaxed condition of the os uteri.

With regard to its frequency, Dr. Radford remarks, "It is happily one of those misfortunes which does not so very often take place; although the writer is inclined to think much more frequently than is generally admitted†. The reason of this concealment is clear, if it is considered what opinion is entertained of the practitioner who has been so unfortunate as to meet with such an event; there is no occurrence which throws more odium upon him, although generally very undeservedly. This feeling paralyzes the energies of the surgeon, and concealment is adopted to shield himself from this unjust imputation‡." Again, "This accident has been attributed to causes purely mechanical, the uterus being unresisting, and passively obedient to their influence. The practice of pulling too early and violently at the funis, after the expulsion of the child, before the uterus has contracted

so as to detach and expel the placenta, has been generally considered as the cause of inversion. But we know that the accident happens before any force has been applied to the funis*. In Case IV. the descent was so rapid and forcible through the pelvis and os externum that it would have been quite impossible to resist the unnatural action by which the organ was carried down†. It has occurred, when the patient had been delivered of a dead child, the funis so putrid as to break with a very slight effort‡. It has been found before the cord was separated, and the child given to the nurse§. In the practice of Ruysch this circumstance took place after he had extracted a dead child, &c.|| These circumstances show that there is a power inherent in the uterus to become inverted. The pulling of the funis is so common a practice amongst our midwives, and done without the least consideration of the condition of the uterus, that if it was so frequent a cause as is usually stated, inversion, instead of being one of the most rare, would be the most common accident in midwifery. Some writers have thought that a short funis is a frequent cause of inversion; whilst others think, in order to act, it must be inserted in the centre of the placenta, and that this mass must be attached to the fundus uteri¶. Now it is evident, if brevity of the cord is capable of producing so serious an accident, these peculiarities will greatly add to its influence. But amongst the published cases of inversion, there is, so far as the writer knows, but one where there this shortness existed**. Inversion often occurs without diminished length in the cord: whilst, on the contrary, children are frequently born where it is very short, and yet no such event happens††. The funis has

been ruptured*, and the placenta disrupted†, and yet the uterus was not inverted.

That the uterus, previous to inversion, is in a state of extreme relaxation, exhaustion, or collapse, and that it offers no resistance to any force applied through the funis, is contrary to the opinion of Dr. Radford, as founded upon an analysis of the published cases, and those related in his Essay. In three of his six cases "the protrusion was forcible, and attended with a strong bearing down pain" (page 13). These facts, with other circumstances, such as that "the fundus and body must at least be so contracted as to represent a body not larger than the size of a child's head," (page 14) in order to admit of its passage through the brim of the pelvis, tend to prove that the uterus is not in a state of relaxation. "It appears to the writer," continues Dr. Radford, "that the uterine pain, diminution of bulk, firm, resisting feel, sudden formation, and rapid protrusion, warrant him in the deduction, that the fundus and body of the uterus, so far from being in a state of collapse or relaxation, are really in a state of unnatural excitement and action. But this is not the case with the os uteri: on the contrary, it is soft and yielding, as we find that it offers no resistance to the coming down of the tumor, whose protrusion is forcible and rapid. If these statements be true, it is evident that the fundus and os uteri are in directly opposite conditions; the former is in a state of violent contraction, the latter in a state of relaxation; and that the relative difference in the two parts of the organ is indispensably necessary to exist where inversion occurs" (page 15). "In the cases of inversion which have been detailed, we find numerous sources of irritation mentioned which are equal to the production of irregular contraction. Hastening the labour‡; artificial rupture of the membranes§; delivery of the pa-

tient in a sitting position*; rapid labour†; mental alarm and agitation‡; hasty extraction of the placenta§; erect position during delivery||; leaning forwards over the bed during labour¶; premature giving way of the membranes**; tedious labour††; pulling at the funis‡‡; to these causes many more might be added, but these are sufficient to show that great mismanagement has existed. They are causes which are capable of hastening or interrupting the parturient process. Many of them are put in force to increase the power of the pains during labour; they have a direct tendency to effect a too rapid, premature, dilatation of the os uteri, and not a less tendency to produce spasmodic and irregular contraction in the womb," (page 18.) "From what has been stated, it may be concluded, that quick labour, whether natural or artificial, a disturbance of this process in any of its stages, or any of those circumstances which produce irregular contraction of the uterus are, singly or combined, the causes of inversion" (page 19.)

"It has been very much the habit," observes Dr. Rigby, in his recent work, "to attribute inversion almost solely to these latter causes," (improper attempts to extract the placenta before the uterus was sufficiently contracted, shortness and twisting of the cord, and delivery in the erect position, with violent jerking or rupture of the cord), "and that, except where it takes place from the shortness of the cord, or the sudden expulsion of the child whilst the mother is in the erect posture, it must almost necessarily be a result of improper pulling at the cord on the part of the practitioner: the cases on record, however, go to prove that in by far the majority of instances no force of this kind had been applied to the fundus; and in those instances where the child has been dashed upon the floor and the cord broken (some six or

respected friend, Dr. Churchill, are strong evidence of the truth of the above statement; and he is glad to have his opinion corroborated by so respectable a practitioner."

seven of which have, at different times, occurred under our notice) the fundus has not once been pulled down, although the force applied to it must have been very considerable, since the very cord which had thus given way to the weight of the child, resisted afterwards, on more than one occasion, a considerable effort which we made to break it."*

It would appear that undue stress has been laid, by most writers on midwifery, upon immoderate pulling at the cord as a cause of inversion of the uterus; and although, as Dr. Rigby judiciously observes, it is not the less important to recommend caution, especially to young beginners, against pulling at the cord with too much force, in their hurry to bring the placenta away, it is to be feared that its spontaneous occurrence is thereby, in some cases, overlooked, and that the most disastrous effects are the result; such as a speedily fatal termination, or the establishment of a permanent and irremediable inversion, followed by a miserable existence for the remainder of the poor patient's life. It is also reasonable to infer that the prominence which has been given to this cause has led to the suppression† of cases which had really come on spontaneously, the publication of all the details of which

might have contributed to more unanimous views as to the causes and other facts connected with the disease.

That immoderate force in removing the placenta may produce inversion of the uterus, there can be no doubt, but if this were the most frequent cause the accident would be of more common occurrence in the practice of midwives*, many of whom, particularly in the country villages, are notoriously ignorant; and such cases would consequently not so rarely come under the cognizance of the medical practitioner.

On looking over the cases which have been published, I have remarked that in many of them the inversion has not taken place immediately after, or simultaneously with, the expulsion of the placenta, and that in many of them the accident has not been recognised until some hours have elapsed, which would be inconsistent with the fact of its being caused solely by pulling at the cord. In my patient every thing was proceeding most naturally until the severe pain was felt (an unusual occurrence in primiparæ), indicative of powerful contraction of the uterus, which took place about twenty minutes after the expulsion of the placenta.

It appears to me, that the uterus, after its contents have been expelled, or with the placenta retained, may be in a state of inertia; that during this condition of the organ, and if the placenta has been expelled, blood may be poured into its cavity from the patent vessels; that irregular contractile efforts may occur to rid itself of the coagula, or of the placenta, if retained; the fundus and body, more particularly the former, being active, and the os and cervix passive, and that thus may the organ become inverted. After the placenta has been expelled, the uterus may contract, and present the firm, hard, and comparatively small tumor above the pubes, as in the case of Mrs. C., and again becoming relaxed, take upon itself an irregular contraction, which may terminate in its inversion.

The possibility of inversion of the uterus being produced, except by pulling at the funis, or by pressure from above, has been denied by Dr. Lee

* A System of Midwifery, p. 319. A few weeks ago, I was called to a person who had just been confined; the cord had been ruptured about three inches from the navel, and the placenta was still adhering to the uterus with the remainder of the cord attached to it, only five inches in length.

Some months ago a case came under my observation in which an unusually large condition of the funis, from an immense accumulation of gelatinous fluid within its cells, rendered the labour tedious and difficult in consequence of its impaction between the head and the brim of the pelvis. The nature of the case was utterly obscure, until, after severe and protracted suffering, the child was born. It is my intention to transcribe it for publication from my case-book (with a sketch of the dropsical cord), but it is merely alluded to in this place because, from the shortening of the cord, owing to the extreme distension of its coats, it bears upon the point under consideration, inasmuch as no inversion of the uterus was produced.

† The reader will not be surprised at such suppression, on referring to the excellent lectures by Dr. Blundell. "We sometimes find, in cases especially which have been mismanaged, that, together with the vagina, the womb is turned inside out" (Lancet, 1827-8, Vol. ii. p. 545). "Should the accident occur to yourselves, which, however, it can scarcely ever do, provided you adhere rigidly to that management of the placenta before prescribed" (Ibid. p. 546). "Remember, therefore, should inversion occur to you (which I hope it will not, for its occurrence is not creditable.)"—*Ibid.* p. 547.

* I have been sent for on three occasions where the midwife had completely detached the funis from the adhering placenta, and in no case did the cord, or placental mass, appear morbidly attenuated or softened: in one case the hæmorrhage from this cause proved fatal.

(Lecture in the *MEDICAL GAZETTE*, Aug. 4, 1843); but, with due deference to the opinions of so high an authority, it is evident to me that contraction of the fundus and upper part of the body of the uterus, without a corresponding contraction, and consequent resistance, of the cervix and os uteri, may produce the effect, even without any other collateral effort: but if we take into consideration the action of the abdominal muscles in the bearing down which has sometimes followed, there can be no difficulty in accounting for the inversion. The arrangement of the moving fibres of the uterus is still involved in obscurity, but there is probably nothing so peculiar in that arrangement as to prevent the upper part of the organ, under a contracted condition, from being thrust within the parietes of the lower relaxed portion, somewhat in the manner one would suppose intussusception of the intestine to occur.* At any rate, for the reasons which have been assigned, and in the absence of arguments to the contrary founded upon a knowledge of the precise anatomical arrangement of the uterine fibres, it is fair to conclude that spontaneous inversion may occur. The indefatigable and distinguished physician who has so clearly unravelled the beautiful and intricate arrangement of the uterine nerves, may yet direct his scalpel to the elucidation of that part of the uterine system which has for so long a time puzzled many of our most profound anatomists, and which is analogous, in its effects at least, to the general muscular system of the animal frame†.

* Irregular contraction of the muscular fibres of the uterus may occur to constitute the hour-glass contraction, when the circular fibres are affected with spasm about the centre of the organ, or even in its upper half. This has been doubted by Rauloquin, Douglas, Schmitt, and other high authorities (see Rigby's *System of Midwifery*), who consider that the stricture is formed by the os or cervix uteri. I have satisfied myself, in two cases which have come under my care, that the contracted portion of the uterus has been perfectly distinct from either the os or cervix uteri, and that they were instances of genuine hour-glass contraction. With the doubts referred to vividly upon my mind, I made a most careful and searching examination in both cases.

† See Dr. Lee's *Papers in the Philosophical Transactions, and Lectures in the MED. GAZ.*

RECORD OF CASES.

By THOMAS MAYO, M.D. F.R.S.

Physician to the Infirmary of St. Marylebone.

(For the *Medical Gazette*.)

[Continued from p. 793 of last vol.]

THE dependence of apoplexy upon disease in remote organs is a subject of much interest. Its occurrence in this kind of connection with pneumonia, is illustrated in the following cases:—

A. B. a large, full, healthy-looking man, aged 54, in the spring of 1843, was brought into Carroll's ward of the Marylebone Infirmary in a state of insensibility, and died almost immediately. It appeared that he had been employed in the workhouse in bodily labour, and seemed in good health up to the moment of his seizure with apoplexy, that morning. He was described as having the day before eaten an enormous dinner of pork, &c. He went to bed apparently well.

Autopsy.—The membranes of the brain were healthy, but the convolutions flattened. A very large coagulum, with some fluid blood, distended the lateral ventricles. The basilar artery was of great size; slight appearances of ossification in many arteries of the brain. The aorta was of great size, but healthy; the heart normal. The right lung almost uniformly in a state of red hepatization; portions from every part of it sinking in water. The left lung gorged with blood, but perfectly crepitant. The stomach very large; no solid contents in it: its walls thin: its surface having a colour exactly similar to that of coffee-ground vomiting. The other viscera healthy.

In a patient of one of my colleagues, who died on the 15th of March, I observed the following appearances on examination the next day. In the upper and anterior part of the right lateral portion of the brain the first slice removed from it disclosed a very large sanguineous effusion, connected with and filling the right ventricle, and a part of the left. Between it and the cortical substance to which it was nearly subjacent, the small intervening portion of medullary substance was softened; and in this softened substance was a large branch of an artery. Whether the patent mouth of this artery was the

breach through which the blood had flowed, or whether it had been divided by the knife, I cannot say. It grated under pressure, and contained small osseous points.

The heart was normal, as were the aortic valves. In the arch of the aorta were small osseous deposits.

The right lung was uniformly and firmly hepatized, of a deep red colour, all but a portion of the upper lobe, which was emphysematous.

All the other viscera were healthy.

On inquiry, I found that this man, aged 78, of a very muscular frame for that age, had been sent into the infirmary from the workhouse on the morning of the 12th, in a state of imperfect coma, having been apparently well the night before. Except during the last 24 hours of his life, he could be roused so far as to answer questions. It was ascertained that he had been in a state of constipation for many days, and the nurse of the ward told me that he was known to be a very large eater. A scruple of the Pulv. Jalapæ c. Hydrarg. Chlorid. had been given him on coming in, and afterwards a drop of Croton oil. His bowels were then largely relieved, with no mitigation of apoplectic symptoms. He vomited, only in the course of the last day, what appeared to the nurse to have a fecal character.

In the first of these cases certainly, and in the latter probably, the pneumonia was antecedent to the apoplexy; in both it may be remarked, with nearly equal degrees of confidence, that the pneumonia ran its course with an insidiousness equally important both as regards the subsequent apoplexy, and the course of the pneumonia viewed on its own account.

On the inquiry set on foot in the spring of 1843, as to a presumed mortality of infants and children in the Marylebone Infirmary, I had occasion to notice to the Commissioners the remarkable freedom from pyrexia, and other customary symptoms of inflammation, with which pneumonia invaded children in the infirmary during spring and the preceding winter. A cough occurred, and a slightly quickened respiration, without any dyspnoea or elevation of temperature. If the stethoscope was applied, after the symptoms had existed a few days, extensive

large crepitation was generally observed over a lobe of the lungs. If at this time the patient sunk and died, extensive red hepatization, with infiltrated pus, was discovered. If the patient lived longer, or finally escaped, the measures conducive to this end were support and a liberal use of wine. When the supporting system was applied early, the child sometimes recovered, though perhaps the gurgling, crepitation, and dullness, had been extremely marked. The breast was very freely taken, as long as the strength lasted, by infants at the breast. In one case of recovery percussion gave almost the feel of a quaggy and wet substance under the percussed surface. Where the attack lasted long, and terminated fatally, tubercular ulceration was generally found in the upper part of the lungs.

Now it must be observed of this state of hepatization, as of that in the first described cases, that it was apparently induced upon principles distinct from that inflammatory turgescence which we presume to attend upon its production in pneumonia. Neither, in these sets of cases, can this be explained altogether on a hypothesis of debility. Many of the children alluded to were no doubt of a strumous habit. But the two adults first mentioned were each powerful and healthy men; in neither of them was there any tubercular deposit.

It is certainly probable that in these apoplectic cases the cerebral disease was mainly induced by the prior embarrassment of the pulmonary circulation. And this suggests additional grounds of attention to the phenomena of the throat in relation to cerebral disease. But may not some prior condition of the brain tending to congestion have rendered the constitution less sensitive under the invasion of pneumonia, and thus have obscured its symptoms?

A cause of this kind may suggest itself, as accounting for the absence of every form of constitutional and local disturbance, except indeed feverishness, in an attack of pneumonia supervening on enteritis, which Andral describes, Observation 59, Vol. I. This case he speaks of as "of the highest interest, and calculated to clear up some points of doctrine which he has not time to develop." The enteritis had been

treated successfully by leeches, &c. ; its overt symptoms had disappeared. Fever after some days set in again, accompanied neither by cough, nor dyspnoea, nor expectoration, nor return of the enteric symptoms. The patient died in four days without any pulmonary symptoms except such as auscultation and percussion developed. The autopsy was as follows, literally translated.

"A part of the lower lobe of the right lung exhibited a mixture of red and grey hepatization: another part of this lobe was red, and being reducible to a pulp by pressure, resembled certain very soft spleens. The rest of the pulmonary parenchyma was sound.

The internal surface of the stomach was white, its mucous membrane of ordinary consistence and thickness. The small intestines presented no visible alteration, till within a foot of the ileo-colic valve. The mucous membrane there was of a brownish colour, as was the cæcum. In the colon there were several white ulcerations, scarcely of the diameter of a pea, the membrane around them white."

Now the case of Eliza Gyon, reported by me in the 541st page of the last volume, illustrates remarkably some effects of intestinal inflammation, presumably, on the functions of the brain, under which the physical symptoms of the fatal disease were entirely masked, as also the moral character of the patient altered. It may be conjectured, though the hypothesis ought to sit lightly, that Andral's attack of pneumonia was rendered "latente" by this kind of influence from the preexisting and accompanying ulceration of the mucous membrane.

In all these cases of pneumonia it may be observed that we are barred of that manner of accounting for phenomena, which the hypothesis of typhoid pneumonia might be supposed to supply. The view adopted by Dr. Williams of this latter disorder, and judiciously described by him in the Library of Medicine, assigns to it a congestive rather than an inflammatory character. "Its products," he observes, "are imperfect and irregular, and neither by the formation of pus nor by the free effusion of plastic lymph is an inflammatory organism manifested." The two first cases in this paper, and those of the children in the Marylebone Infirmary, were cases in which the agglutination into

a firmly hepatized state was perfect, and pus freely effused; and in Andral's report we find both "red and grey hepatization." His practice moreover was depletory and antiphlogistic in that attack.

[To be continued.]

CHOLERA IN INDIA.

To the Editor of the Medical Gazette.

SIR,

THE communication of Mr. Rankin, of the General Hospital of Calcutta, on the treatment of cholera, brings forcibly to my memory the short experience I had of that disease in India. Entertaining similarity of views on the treatment, I hope I may not occupy your pages unnecessarily in adding my mite to the more extended experience of Mr. Rankin.

During May 1830 the shipping in Bombay Harbour suffered from an aggravated attack of epidemic cholera. I may particularly notice the H. C. S. Berwickshire, which lost 40 men out of a company of 150 in a very few days. The H. C. S. Orwell (in which I served as assistant surgeon) had her share, but to a much less extent; for although we suffered severely from general sickness, we had not more than twelve reported cases of cholera, all of which were treated on the principles advocated by Mr. Rankin; our sheet anchor was the vapour bath, and venesection whilst in the bath, but not until reaction took place, for we always considered it a waste of time to administer any internal medicine. Two cases, one fatal, the other recovering, were then strongly impressed upon my memory, for I regret that no notes were kept, except the regular medical journal of the ship, arising from the onerous duties that devolved upon me in consequence of my colleague being one of the first attacked; but the history of these, and other cases of cholera, treated principally by the vapour bath, are now in the medical archives of the East India Company.

The subject of the first case was the gunner of the ship: on his application we attempted to bleed, but failed, when we immediately put him in the vapour bath, regulating the heat according to his feelings, and in half an hour's time

completely removed his acute sufferings. After reaction (which I believe in a properly regulated bath will never fail to be produced) he was bled, and kept for upwards of an hour in the bath; he was then removed and placed between hot blankets; calomel and opium were administered; the case appeared in every way to go on favourably. A few hours after his removal from the bath, however, we had strong head symptoms. My colleague Mr. Bremner, the surgeon of the ship, remarking "now is the time to open the temporal artery," he left me for two minutes, to procure a lancet for that purpose, but before he returned, the man dropped suddenly in my arms, and died. Never shall I forget the chagrin I felt in losing this my first case of cholera, just when we believed our efforts would be crowned with success. However, encouragement was given us to persevere, and it was not many hours ere an equally severe case presented itself: no time was lost in placing our patient in the bath, and letting in a strong current of hot air, to the almost immediate relief of his suffering; the poor fellow exclaiming "he was in heaven." I may mention in this case I placed Fahrenheit's thermometer on his abdomen, and found it as high as 150°, and that without causing any disagreeable symptom, with the exception of slight scalding of the shins, with which the hot air came in more immediate contact: he was also bled until syncope was produced: similar reaction took place, calomel and opium were administered, with the application of cold to the head, and in a few days complete recovery took place. From the after experience I had of cholera I felt fully convinced that the external application of heat, so as to produce reaction, was the only means that could be depended on in this formidable disease. The question is, whether the application of hot salt bags, hot or vapour baths, ought to have our preference, and I should certainly give it to a well-regulated vapour bath, the heat being more equally diffused, and the patient being capable of bearing heat in this manner at a much higher temperature than by any other application.

In all the medical nosologies we find the disease cholera placed amongst the diseases of the digestive organs, as its name implies; but in my opinion the

rice-water stools, the deficiency of the urinary secretion, and the collapsed state of body, are only the effects of a cause which arises from the quantity and quality of the blood sent to the different parts of the body; I therefore should consider it ranked more properly amongst diseases of the circulating system. I would refer to the excellent remarks of Mr. Annesley, who hazards an opinion of the blood not receiving sufficient quantity of oxygen from the atmosphere.

During the epidemic I mention, there was a symptom that occurred at what might be termed the stage of invasion, which I do not remember as being particularly noticed by any author, but which we remarked in every patient that applied to us at this early stage: an uneasiness in the frontal region, with a vacuity of thought, and this was complained of some hours previous to any disorder of the biliary system. I can corroborate, most fully, the observations of Mr. Annesley on the subject of the stage of invasion; our men were fully warned to make early applications for medical advice, and on seeing them at this stage we used the lancet freely, with drastic purges, and, I trust, not without success.

The vapour bath used was one invented and made by my ingenious friend, Mr. Bremner, the surgeon of the ship. But I fear I have engrossed too much of the valuable space of the *MEDICAL GAZETTE* in giving my "Random Recollections" of this formidable disease.—I am, sir,

Your obedient servant,

GEORGE B. CLARK, M.D.

Member of the Royal Colleges of Surgeons of London and Edinburgh.

Trinity Street, Colchester,
26th March, 1844.

EFFECTS OF OPIUM ON INFANTS.

To the Editor of the Medical Gazette.

SIR,

HAVING, in your number for March 8th ult., read the remarks on the effects of opium on infants, I am induced to send you the following case, which, however, by its favourable termination, has perhaps lessened the medical interest which attaches to it.

Feb. 25th, 1844, about 1 P.M.—Mr. C——'s infant, a fine little girl,

æt. 10 months, having been allowed to play with some pills (Pil. Sapon. c. Opio, gr. v., Ex. Colo. Co gr. vii. in Pil. iv.) which were silvered over, the nurse observed the child making a noise, and as if swallowing something with difficulty: suspected some of the pills were taken. One pill was found in the child's dress, and one in the pill-box, but there were four, and after sweeping the room, and the most careful examination, the other two were not found. I was present within a quarter of an hour; the child was then playing, cheerful, and in perfectly good health; however, from the account of the case, I thought it right to act, although in doubt. The opium swallowed being in the form of pills, and the pills having been made a long time, instead of using the stomach pump I administered immediately half a scruple of the sulphate of zinc dissolved in a very small quantity of warm water; this not producing vomiting in a quarter of an hour, I gave Ant. Pot. Tart. gr. ii., which was repeated every ten minutes to the fourth time. Tickling the posterior fauces with a feather was also had recourse to, with occasional draughts of warm water, but all without avail. About half an hour after the last dose of Tartar Emetic, when almost giving up in despair of causing vomiting, it suddenly occurred, and by the use of warm water was then kept up. The food of the day was returned, and with it some dark substance which proved to be portions of the opium pills; one piece the size of half a pill, the others divided and mixed with the food, having the smell of opium. Pieces of the silver leaf were also found, leaving now no doubt, and from the quantity showing most probably that two pills were swallowed. After the vomiting had subsided, a teaspoonful of castor oil was given, which in the evening acted, and no appearance of the pills in the motion, which was healthy. The child did not appear drowsy; in fact, its parents thought it more lively than usual. Slept comfortably during the night, and was quite well next morning, neither suffering from the opium, nor from the emetic remedies that had been administered.

The only remarks suggested are these: 1st, the large doses of emetics which were given for a time without success; this may be accounted for,

doubtless, by the action of the opium on the nerves of the stomach, but yet there was an absence of any other symptom on the nervous system; and 2d, the total absence of any irritation produced either by the zinc or tartar emetic on the mucous membranes afterwards.—I am, sir,

Your obedient servant,

CHARLES TAYLOR, M.R.C.S.

March 28, 1844.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

The Chemical and Physiological Balance of Organic Nature. By M. J. DUMAS and M. J. B. BOUSSINGAULT. 3d edition, pp. xii. and 156, post 8vo. Baillière.

WE have been acquainted for some time with this elegant essay in the original, and are well pleased to meet with it now in an English dress, satisfied that it is singularly well calculated to diffuse correct and pleasing views of the harmony of nature in all her parts, and to raise the mind through every-day pursuits to the contemplation of things higher, holier, than we have the happiness of being at all times brought into contact withal.

Vegetables, animals, man, contain matter in their composition. Whence comes it? what part does it play in their tissues? what becomes of it when death breaks the chain by which its various parts and forms were so closely conjoined?

Such are the questions which our authors ask; the business of their essay is to resolve them; and the two grand resolves of nature—the animal and the vegetable, are placed in the balance, the atmosphere being as it were the medium of connection between them, and weighed one against the other. Vegetables are shown, save in rare circumstances, to constitute apparatuses of reduction; animals to be invariably instruments of combustion. Vegetables reduce carbon, hydrogen, and nitrogen, from carbonic acid, water and oxide of ammonium. Animals, again, exhale carbonic acid, hydrogen in the form of water, and nitrogen in the shape of urea. Vegetables evolve

oxygen, and produce neutral azotized substances; albumen, fibrine, gluten, fatty substances, starch, sugar, and gum. Animals consume oxygen, neutral azotized substances, fatty matters, starch, sugar, and gum. Vegetables still further absorb and fix the light and heat of the sun. Animals produce heat; vegetables derive their elements from the air, the earth, or the water. Vegetables finally transform mineral matters into organic matters; animals turn organic into mineral matters.

"Of all the elements of modern chemistry, organic nature makes use of but three or four; of those vegetable and animal substances which are now multiplied almost to infinity, general physiology requires no more than some ten or twelve species; and all the phenomena of life, so complex in appearance, may be referred, in their essence, to a single general formula.

"We have, in fact, found, by a multitude of results, that an animal, in a chemical point of view, constitutes a true apparatus of combustion, by which carbonaceous matters, burnt incessantly, are returned to the atmosphere in the shape of carbonic acid; in which hydrogen, burnt incessantly, is returned as water; whence, in fine, free azote is ceaselessly exhaled in the breath, and, in the state of oxide of ammonium, is thrown off in the urine. From the animal kingdom, therefore, as a whole, carbonic acid, watery vapour, and azote or oxide of ammonium, are continually escaping.

"We have, on the other hand, found that vegetables, in their natural and healthy state, decompose carbonic acid incessantly, fixing the carbon, and setting free the oxygen; that they decompose water, seizing on its hydrogen, and disengaging its oxygen as before; lastly, that they either abstract azote directly from the air, or take it indirectly from oxide of ammonium or nitric acid; thus acting, in every particular, inversely or in opposition to animals. If the animal kingdom constitute an immense apparatus of combustion, the vegetable kingdom, in its turn, constitutes an immense apparatus of reduction, where carbonic acid decomposed leaves its carbon, water its hydrogen, and oxide of ammonium and nitric acid their ammonium or their azote.

"If animals incessantly produce carbonic acid, water, azote, and oxide of ammonium; vegetables consequently consume, without cease, oxide of ammonium, azote, water, and carbonic acid. What the one gives to the atmosphere, that the other takes from it; so that, surveying these facts from the loftiest point of view, and in connexion with the physics of the globe, it would be imperative on us to say that, in so far as their truly organic elements are concerned, plants and animals are the offspring of the air; that they are but condensed or consolidated air; and that, to form a true and accurate idea of the constitution of the atmosphere at the epochs which preceded the birth of organized beings, it would be necessary to restore to it, by calculation, the whole of the carbonic acid and azote, the elements of which were appropriated by vegetables and animals when they appeared.

"Vegetables and animals, therefore, come from the atmosphere, and return to it again; they are true dependents of the air.

"Vegetables assume from the atmosphere the elements which animals exhale into it; viz. carbon, hydrogen, and azote, or rather carbonic acid, water, and ammonia.

"But how do animals procure the elements which they give to the atmosphere? Let us inquire particularly into this point. Now it is impossible to contemplate, without admiration, the sublime simplicity of the laws of nature here, as every where! Animals always derive their elements primarily from vegetables.

"We have found, in fact, by results beyond the reach of question, that animals do not create any of the truly organic substances, but that they consume or destroy them; that vegetables, on the contrary, habitually create these substances, and that they destroy but few, and this only for particular and determinate ends.

"It is in the vegetable kingdom, therefore, that the great laboratory of organic life is found; it is there that both vegetable and animal substances are compounded; and they are all alike formed at the cost of the atmosphere.

"From vegetables these substances pass ready-formed into the bodies of

herbivorous animals, which destroy one portion of them, and store up another in their tissues.

"From herbivorous animals they pass ready-formed into the bodies of carnivorous animals, which destroy or lay them up according to their wants.

"Finally, during the life of these animals, or after their death, the organic substances in question return to the atmosphere from whence they originally came, in proportion as they are destroyed.

"Thus is the mysterious circle of organic life upon the surface of the globe completed and maintained! The air contains or engenders the oxidised substances required,—carbonic acid, water, nitric acid, and ammonia. Vegetables, true-reducing apparatus, seize upon the radicals of these, carbon, hydrogen, azote, ammonium; and with them, they fashion all the varieties of organic or organisable matters which they supply to animals. Animals, again, true apparatuses of combustion, reproduce from them carbonic acid, water, oxide of ammonium, and azotic or nitric acid, which return to the air to reproduce the same phenomena to the end of time.

"And if, to this picture, already so striking by its simplicity and grandeur, we add the indubitable part performed by the solar light, which is alone possessed of power to bring into play this immense, this unparalleled apparatus, constituted by the vegetable kingdom, in which the oxidized products of the atmosphere are subjected to reduction, it is impossible not to be struck with the import of these words of Lavoisier: 'Organisation, sensation, voluntary motion, life, only exist on the surface of the earth and in places exposed to light. It might be said, indeed, that the fable of Prometheus was the expression of a philosophical truth, which had not escaped the penetration of the ancients. Without light, nature were without life and without soul: a beneficent God in shedding light over creation strewed the surface of the earth with organisation, with sensation, and with thought.'

"These words are as true as they are eloquent. If sensation and thought, if the noblest faculties of the soul and the understanding require a material vesture for their manifestation, vegetables are the labourers charged with the task of building it up, and from elements which

they derive from the air, and elaborate under the influence of the light which the sun, its inexhaustible fountain, pours in ceaseless floods upon the earth.

"And, as if all in these grand phenomena were destined to be associated with causes which should appear the most remote, we may here observe upon the sources whence the oxide of ammonium and azotic acid, from which vegetables derive a portion of their food, are themselves derived. They are in fact, produced upon the grand scale by the action of those magnificent electric sparks that dart from the storm-cloud, and, furrowing vast fields of air, engender in their course the nitrate of ammonia, which analysis discovers in the thunder-shower. As it is from the mouth of volcanoes, then, whose convulsions so often make the crust of our globe to tremble, that the principal food of plants, carbonic acid, is incessantly poured out; so it is from the atmosphere on fire with lightnings, from the bosom of the tempest, that the second and scarcely less indispensable aliment of plants, nitrate of ammonia, is showered down for their behoof.

"Might it not be said that we have here a remembrancer of that chaos mentioned in the Bible, of those periods of tumult and disorder which preceded the appearance of order and organisation upon the earth?

"For, scarcely are carbonic acid and nitrate of ammonia formed, than a calmer, though not less energetic force, begins to act upon them for new purposes: this force is *light*. By the agency of light, carbonic acid yields up its carbon, water its hydrogen, nitrate of ammonia its nitrogen. These elements combine, organic matters are formed, and the earth is clothed with verdure.

"The atmosphere presents itself to us as including the primary materials of all organisation. Volcanoes and thunder-storms meet us as the laboratories in which are compounded the carbonic acid and nitrate of ammonia which life requires for its manifestation and extension.

"Light arrives, and with the concurrence of carbonic acid and nitrate of ammonia, the vegetable world, the grand producer of organic matter, is developed.

"Then come animals, consumers of

matter, and producers of heat and of force, true instruments of combustion. It is in them, unquestionably, that organised matter acquires what may be called its highest expression. But it is not without detriment to itself that it becomes the instrument of sensation and of thought. In this new capacity organised matter is burnt; and in giving out the heat or electricity which constitutes and is a measure of our force, it is destroyed, and returned to the atmosphere from whence it had originally come, whilst its caloric is radiated into space, and goes to supply that which vegetables had absorbed and fixed.

"Thus all that the atmosphere yields to plants, plants yield to animals, animals restore to the air. Eternal round, in which the inanimate is quickened and life appears, but in which matter merely changes its place and its form!"

But we have quoted enough from this delightful work to show its bearing and its style; we invite our readers to read it as a whole, nowise doubting that they will then be disposed to esteem it as highly as we do ourselves.

MEDICAL GAZETTE.

Friday, April 5, 1844.

"Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri; potestas modo veniendi in
publicam sit, dicendi periculum non recuso."

CICERO

OUR NEW VOLUME.

IN commencing another volume of the LONDON MEDICAL GAZETTE, we have pleasure in addressing a few words to our contributors in particular, to our friends and readers in general. *Semper idem* might be our motto, so uniform seems our series upon the shelves before us—in form, at least, we have not sensibly altered since we came into life, it is now some sixteen years ago. And when we turn to our pages we believe that we see the same spirit pervading them at the present hour which actuated them at first; for it has still been our aim, as it was our primary purpose, to serve as the organ of the science and

the practice, rather than of the politics of our profession. Not that we have entirely neglected medical politics either; freedom of opinion, and some means for the expression of that opinion, are so essentially parts of our existence in this atmosphere of Britain, that it was impossible for us to pass by without comment such events as were interesting to us as a body, numerous, respectable, and silently influential through our intellect and our acquirements. Medical politics have always been freely, though temperately, discussed in the pages of the MEDICAL GAZETTE; for we have neither been hurried into revolutionary extremes by recklessness and passion, nor yet have we been indifferent to the progress of events, or held at all times, that "that which is, is best." The frame of universal nature is upheld by change, and society is never precisely that to-day which it was yesterday; nor will it be to-morrow that which it is to-day: old forms must be replaced by new, suited to the varying circumstances in which every successive generation of man is placed.

Our main object, however, shall be, as heretofore, to provide for our readers intellectual fare of the best. In our last number we hinted at certain negotiations that were in progress with more than one distinguished professor, both at home and abroad, abstracts or more extended reports of whose prelections it is our purpose to give. We also intend to take in a wider circle than hitherto of the medical periodicals of France and Germany, from whence to glean information, new, interesting, and important to our readers. We shall also do our best to give a regular bibliographical record of all the publications on medicine and the collateral sciences which appear on the Continent as well as in this country.

Whilst, therefore, we solicit the

unabated support of old, and the aid of new contributors, we promise, for our own part, to do all in our power to uphold the honour, and to extend the usefulness, of the medical profession.

GRADES IN PROFESSIONS.

Do professions truly admit of grades among their members? We apprehend, though custom may have sanctioned them, that in reason they do not. Grade implies relative superiority and inferiority determined on grounds other than that natural disparity between man and man which is connected with original endowment. There is, it is true, work of different kinds to be done; and therefore have we different branches in professions generally: in the law, barristers, solicitors, notaries; in medicine, physicians, surgeons, apothecaries. But grade in each class is scarcely to be conceived. Barristers are all called upon a footing of perfect equality, and it is left for the best man to get foremost in the race. The idea of grade among our highest legal advisers, other than that which is achieved by abilities or standing, even appears absurd: should we be content to have for our legal guides one set of men less thoroughly informed on all knotty points of the law than another? Would it be reasonable that among barristers there should be one grade where we might hope to resolve us of our doubts and learn our rights according to statute and immemorial usage, and another grade where any such resolution, any such information as that we were in quest of, was not to be expected? Yet all this would be implied in the existence of gentlemen of different grades practising at the bar.

The medical profession has not, like the law, excluded grades, among the different classes of its practitioners.

Among the physicians, grades seem to have existed from the establishment of their College, and doubtless they also obtained long before that event. The surgeons, too, in former times, must have had grades; one set appear to have confined themselves to surgery, properly so called; another associated what are now held to be the humble offices of the barber with their higher duties. The surgeons, however, by and by became ashamed of their alliance with the barbers, procured a statute of separate incorporation, and fled from the common hall, leaving their old associates in possession of all the records, goods and chattels: they fairly went off empty-handed. Surgery, however, now freed from menial offices, made rapid strides in improvement; but from about the middle of the last century up to the present time without distinction in regard to grade, among the members of her Corporation first, of her Royal College in London next.

The College of Physicians have, for the last quarter of a century in particular, been gradually relaxing in their distinctions as to grade—the difference was a perpetual source of contention between men, mostly of equally liberal education and of like professional knowledge, who met everywhere save at the College on a footing of perfect equality. By and by the distinction between Fellow and Licentiate must have ceased of itself to be.

The College of Surgeons, strangely enough, seem disposed to adopt that which the College of Physicians have been abandoning—a distinction into grades. Will not this distinction, however, be found an apple of discord in the surgeon's, as it proved to be so long in the physician's branch of the profession? Will it not seem to sanction a difference of acquirement, a less and a greater amount of education as

admissible in circumstances where the *greatest* is never more than enough? We doubt, we fear for the ultimate effects of a distinction into a higher and a lower grade in surgery. Already the general practitioner is suspicious, and even complaining that the College of Physicians and the College of Surgeons are in league to degrade him. But then it is stated on the best authority, that the Council of the old College of Surgeons in London were left no choice—they must needs make a change; the step was forced upon them by the Minister. They have, of course, recommended an arrangement which they believe will not merely be productive of the least mischief, but which will do most to maintain or exalt the character of the profession. That this may be its effect is our most fervent prayer.

ROYAL MEDICAL & CHIRURGICAL SOCIETY.

• Tuesday, March 26, 1844.

THE PRESIDENT IN THE CHAIR.

Notes of a case of Vitiligo Infantilis. By GEORGE GREGORY, M.D. Physician of the Small-pox and Vaccination Hospitals.

THE case was that of a child 13 months old. At the age of 4 months the mother first noticed about its neck some smooth, white, shining elevations, which continued to spread. At present these tubercular elevations, varying in size from that of a pea to a small wafer, and of irregular form, occupy the neck, back, and a large portion of the abdomen. A few of these terminate by tubercular vesicles on the summit of the tubercle, and a small scab succeeds. The child is in good general health, is at present cutting its teeth, and the process of dentition goes on favourably. The author observes, that it cannot be doubted but that the vitiliginous state of the surface is connected with the process of dentition. Like strophulus, and other cutaneous diseases, it serves a very useful purpose in the infantile economy. The action of vessels which is here harmlessly expended upon the surface, might if transposed to an internal organ lead to serious results. When dentition continues, he considers it would be impossible

to put a sudden check to the disease, and unwise to do so, if it were possible.

The infant itself was shown to the Fellows of the Society, and also a very beautiful and correct wax model, illustrating the present appearance of the disease.

On Dislocations of the Astragalus, with the lower ends of the Tibia and Fibula inwards, illustrated by cases. By HENRY HANCOCK, Esq., Surgeon to the Charing-Cross Hospital.

THE object of this paper is to direct attention to an injury of comparatively rare occurrence—dislocation of the astragalus from the os calcis and scaphoides, the ankle-joint remaining entire. The writer, after alluding to numerous authors who considered that such an accident could not occur, gives an account of the only four cases he has met with in the works of various writers, viz. two in the last edition of Sir A. Cooper's work on Dislocations and Fractures, edited by Mr. B. Cooper; one related by Professor Harrison in the Dublin Journal, Vol. XV., designated "Displacement of the Foot outwards, with Fracture of the Fibula;" and a fourth described by Dupuytren in the *Leçons Orales*, Vol. I. p. 225, as "a fracture of the fibula with dislocation of the foot inwards." Both these latter titles the author considers erroneous; for it is very doubtful whether, in reality, the astragalus with the lower ends of the tibia and fibula are not the parts displaced; and even if this be not the case, it is only a portion and not the whole of the foot which is dislocated.

The following cases are related by the author.

John Middleditch, a strong healthy man, æt. 24, was admitted into the Charing-Cross Hospital, under the author's care, on the 5th of December, 1840, with an injury to the right ankle, having fallen from the top of one of the vats in a brewery. Four days afterwards, when the swelling was reduced, it was found that the fibula was fractured about three inches above the ankle; the axis of the tibia, instead of falling on the centre of the foot, was thrown inwards and slightly forwards, giving the leg the appearance of being twisted in that direction. The position and direction of the foot were not materially altered, further than by its projecting considerably on its outer side and the toes turning slightly outwards, but its dorsum looked upwards as in the natural condition. Upon carrying the finger along the outer edge from the heel forwards, the anterior extremities of the os calcis, where it unites with the cuboid bone, could be felt distinctly, whilst above there was a considerable cavity instead of the prominence formed by the astragalus and external malleolus. By press-

ing the finger along the dorsum of the foot, a depression could also be distinguished behind the posterior margin of the scaphoid bone. On the inner side of the foot was a prominence corresponding to the internal malleolus, of which the inferior margin could be distinctly defined; and anteriorly and inferiorly, another projection, more prominent, evidently caused by the head of the astragalus, over which the skin was tense, thin, and vesicated. The distance between the internal malleolus and prominence of the os calcis was somewhat greater than in the sound foot, and that between the lower end of the inner malleolus and the sole of the foot diminished above an inch. The ankle-joint was still capable of flexion and extension, and there was very considerable motion in the centre of the foot, corresponding to the calcareo-cuboidal articulation, forming as it were a double joint. It was concluded that the astragalus had been forced from without inwards, off the upper articulating surfaces of the os calcis, carrying with it the lower ends of the tibia and fibula, most probably resting upon the lesser process of the os calcis. The various steps by which reduction was effected are next described.

The integuments over the point of pressure sloughed and separated on the third day after the reduction, leaving the anterior part of the astragalus exposed in its proper position; and this was succeeded by considerable discharge for several days, in the course of which, the internal calcareo-scaphoid ligament sloughed and came away; the astragalus being now no longer restrained in that direction, gradually twisted round upon the calcis, until at length a large portion of its head protruded through the opening in the integuments: this prevented the wound from closing, and as the bone could not be kept in its proper position, but had lost its articular cartilage, and was passing into a state of necrosis, he subsequently, with a small saw, removed its head to the extent of about three-quarters of an inch; after which the wound gradually healed, the parts became consolidated, and the man left the hospital cured in July, just seven months after the accident.

Ten months subsequently the following report was made:—He walks as well as he did before the accident, without stick, or artificial support of any kind. The leg is larger than the opposite one, and there is some thickening around the ankle; but the motion of the joint is good, and the direction of the foot and the situation of the malleoli natural: he is able to do his work, which at times is very heavy, as well as ever he did; his leg being entirely free from pain.

The particulars of the last case are taken from the surgical notes of the late Mr. Howship, and relate to a preparation in the possession of the Royal College of Surgeons.

It appears, from the position of the bones, that the same accident had occurred as that described in the former case; but that the dislocation had not been reduced. The author enters into a detailed account of the bones. He then concludes his paper with some observations on the treatment to be pursued in these accidents, giving the opinions of various writers on dislocation of the astragalus.

Mr. Lloyd made some general observations on the subject of the paper, and particularly combated the propriety of amputation, save in extremely rare and desperate circumstances. In the vast majority of instances of dislocation of the astragalus, amputation, as it was not required, so was it altogether inadmissible. In former days, indeed, the operation was even commonly had recourse to; it was one of the old canons of surgery that it should be so; and he quoted the case of a late governor of Newgate, whose leg he had himself, when a young man, dissected, after it had been removed by a couple of old surgeons, where he found the injury so trifling, that he plainly saw the step which had been taken as altogether unnecessary.

Mr. Hancock, who seemed to have mistaken the tendency of Mr. Lloyd's remarks, adopted them as justifying the amputation which he had advocated. Mr. Lloyd explained, and Mr. Hancock was somewhat tart in his reply to the surgeon of St. Bartholomew's.

Mr. Quain directed Mr. Hancock's attention to the true bearing of Mr. Lloyd's remarks, who had, in fact, quoted the amputation which had been performed on the Newgate governor as an instance of antiquated surgery—a practice which certainly would not generally be imitated in the present day.

Mr. Davies related an anecdote of Mr. Abernethy, whose surgery was always largely tempered with humanity, and who never took up the knife without regret:—A London merchant had suffered a dislocation of the astragalus at some considerable distance from London, where, we presume, Mr. Davies was at that time settled in practice. Mr. Davies recognized the nature of the injury, and, aware of the delicate point of surgery he had to deal with, he recommended a consultation. Mr. Abernethy was selected by the patient, and he arrived at Mr. Davies's house about two o'clock in the morning, his whole travelling baggage consisting of a shirt tied up in a pocket-handkerchief. Though he arrived at two o'clock, Mr. Davies, nevertheless, found him up and walking in the garden when he put out his own head between five and six. On seeing the patient, Mr. Abernethy approved the temporizing measures that had been pursued,

totally repudiated amputation, and took his leave. The patient made a good recovery; and if he did not gain a leg that was as supple about the ankle-joint as the other, he still had a limb which was a great improvement upon a wooden one, and that served him to stump about for many a long year afterwards.

Case of Obstruction in the Intestinal Canal, terminating favourably on the ninth day by spontaneous vomiting and evacuation of the intestine's contents. By Sir GEORGE LEFEBVRE, M.D.

THE subject of the present case was a little girl of twelve years of age, of a very delicate constitution, strongly marked scrofulous disposition, and with very feeble digestive powers, so that she was unable at all times to digest fruit or vegetables. She had been attacked by an epidemic autumnal cholera, which prevailed amongst children in the town where she was residing, and which yielded to the usual mode of treatment. Soon after the termination of this, she was attacked by a disease of an opposite nature, and became obstinately constipated, whilst the stomach rejected every thing that was taken in. Purgatives had been employed in every shape, but without effect; leeches had been applied to the abdomen, which had been fomented freely.

Such was the history of the case, which I received from the two medical men in attendance previous to my seeing her. I saw her on the 27th of August in the afternoon. She was much flushed in the face, had an anxious countenance, a small, quick, compressible pulse, a cold, moist surface, the extremities being colder than natural. She suffered from distension of the abdomen, without complaining of much pain, and she vomited continually a green bilious-looking fluid. As no inflammation was apparent, and as more depletion was not, under the existing circumstances, indicated, soothing measures were employed. The vomiting was the most annoying symptom, from its frequency rather than from any distress which it occasioned, for this dark-green fluid was thrown up without much effort. A small blister was applied to the pit of the stomach, and small doses of prussic acid administered in almond-milk. This treatment seemed to check the vomiting for many hours successively. She passed a tranquil night, but no relief to the bowels had been obtained by stool, and the abdomen was much more swollen. Croton oil was given internally and in clyster during the day, and as warm applications seemed to have no effect, bladders filled with ice were applied all over the belly. The patient was restless and uneasy, continually changing her place in bed, but this arose from distension rather

than from any acute pain. About midnight of the 28th, she complained of twisting and severe pain in the bowels, of a colicky nature; there was also more pain upon pressure than previously, and as opiates were administered without benefit, I applied a dozen leeches to the abdomen with immediate relief to the distressing symptoms, which subsided soon afterwards. She got some sleep, and was free from pain when awake. I was obliged to return to London, and did not see her again till the afternoon of the following day. I learned from the physician in attendance that she had passed the day on which I left her pretty well, but that at midnight the same symptoms recurred as on the night previous, and, notwithstanding her state of great exhaustion, he had again applied leeches with benefit. He informed me that the vomiting had returned, and that the matter brought up was evidently from the ileum, and the seat of the stricture seemed to be about the caput cæcum.

There was no question, upon minute examination, that the matter vomited up proceeded from the small bowels. The distension was now very great, respiration was much impeded, and the little patient suffered severely. A long elastic tube was introduced into the rectum, and which was carried into the colon, into which water was forced by a pumping syringe. The operation was productive of great distress to the patient, and was ineffectual as to relief. The night was restless, and the following day the little sufferer seemed much exhausted. The face was colourless, the countenance anxious, the body covered with a cold clammy sweat, and she expressed herself as if about to die. The bed-room having a southern aspect, and the weather being sultry, I desired that she might be removed into a cooler room. She was carried in the arms to bed, and as she was much fatigued by the operation I gave her a glass of Madeira wine, which she drank with pleasure, but hardly had she swallowed it, when she made signs for the basin, lifted herself up in bed, and threw up a dark green fluid to the amount of three pints. She experienced immediate relief, and breathed more freely, and the upper part of the body became more loose and compressible. I gave her some more wine, which remained on her stomach; she had no more nausea. Constant friction was maintained over the abdomen, and injections of vinegar and water were repeated every hour. The first was returned without being accompanied by any solid matter, but had a foetid smell. The second was accompanied by pieces of flocculent matter of a membranous appearance, and the fluid returned was horribly foetid, like putrid water in which flesh had been macerated.

She was now enabled to compress the ab-

dominal muscles and make an effort to go to stool, which the previous great distension paralysing the action of the muscles had prevented her from doing. Much of this membranous matter came away after each injection. The smell was most offensive. About four hours after the spontaneous vomiting she asked to go to the chair, when the bowels gave way, and a large quantity of solid excrement was voided. She passed several more stools in the course of the evening, and then slept tranquilly. The following morning I gave her a dose of castor oil, which produced its desired effect without creating nausea, and I left her convalescent: I learned subsequently from my colleagues that she had a good deal of constitutional fever for four or five days. She recovered in a short time, and her digestive powers are now better than previous to her illness. The obstruction was relieved only on the ninth day of the disease.

Sir George Lefevre said that he was moved to submit the history of this case of recovery from a most formidable disease, on account of the rarity of such an occurrence. He thought that many interesting single cases were lost to the profession, from want of such a record as he had made of the one just read. It ought not always to be the object of members of the Medico-Chirurgical Society to write connected treatises, with a special view to their publication in the *Transactions*.

ON DIFFERENT FORMS OF GRANULAR DISEASE OF THE KIDNEY.

By J. D. HEATON, M.D.
(*For the London Medical Gazette.*)

IN looking over my reports more carefully, I find three other cases in which the symptom of albuminous urine coexisted with other disease, and which, as occurring in the same hospital, and during the same period, may form a not improper sequel to those already related.

Alexander Norman, age 29, admitted under Dr. Williams, June 24, 1841: a canal boatman, of middle stature, stout, but of clumsy conformation, and strongly marked with signs of the scrofulous diathesis, having scars under the lower jaw, and enlargement of the ends of the fingers and of the ankles and wrists, apparently of a scrofulous character.

His occupation exposes him much to the weather, and he has been for some years subject to a cough, with pain in the chest, and bloody sputa. For the last six months he has had swelled feet; he has had frequent pain in the loins; the urine has gene-

rally been high coloured and scanty, though he has had very frequent calls to discharge it; occasionally, however, it has for a time become very copious and pale, again returning to the former state.

Six weeks ago he got wet through, and caught a severe cold; the usual symptoms of inflammatory fever followed, and he had much pain in the right side of the chest, with shortness of breath, cough, and expectoration of sputa streaked with blood.

These symptoms have continued from that time. At the time of his admission the feet are cedematous, the face appears swollen, the urine is high coloured, rather scanty, of a low specific gravity, and strongly albuminous, both as tested by heat and by nitric acid. The pulse is of natural frequency, and quite soft; the tongue covered with a very thin white fur. The physical signs give decided proof of the existence of pneumonia. In the right side of the chest there is extensive dullness of stroke-sound; tubular breath-sound; obscure respiratory murmur. In the left side there are the signs of a small cavity in the apex of the lung, and slight crepitation at the base posteriorly.

For these symptoms he was cupped in the right side; he took a dose of calomel, followed by the ordinary senna draught, and commenced the use of a saline mixture having half a grain of tartar emetic in each dose. Under this treatment he was considerably relieved, and for some time improved gradually. During his stay in the hospital, however, he had two relapses, the chest symptoms becoming more acute, accompanied with some febrile reaction, so as to require, temporarily, more decided antiphlogistic treatment to be repeated.

The urinary symptoms always remained much the same. He had occasional though not severe pain in the loins; the cedema was never removed; the urine was strongly albuminous at all times, below the average quantity, varying in specific gravity from 1010 to 1020.

The antimonial mixture was continued throughout his stay in the hospital; Tr. Cantharidis was subsequently added to it, but without any decided effect on the urine.

At the time of his discharge, the dull stroke-sound, and the crepitation at the base of the lungs, were both diminished; but the signs of tubercular congestion and condensation remained under both clavicles, and of a cavity under the left clavicle. The urine was small in quantity, paler than formerly, specific gravity 1007, and contained much albumen. He was discharged at his own request, July 22d, having been in the hospital seven weeks.

John Williams, age 63, admitted under Dr. Williams, June 19, 1841; he is a porter,

of short stature, spare habit, and rather decrepit appearance.

Previously to his becoming an in-patient, he has been under treatment for three weeks as an out-patient, for symptoms of congestion of the brain. At the time of his admission he was in a half comatose state, with considerable jactitation of the limbs; incapable of answering coherently, but with the pupils obedient to light. There was great oppression of the breathing, and a frequent feeble cough; a loud, sonorous, and mucous rhonchus was audible even at some distance from the patient, but at this time no crepitation could be distinguished. There was extensive dulness of stroke-sound over the right chest; the left side was more resonant, and a loud puerile respiration was heard mixed with the rhonchus. There was extensive dulness over the cardiac region; the loud respiratory rhonchus obscured the sounds of the heart in the first place, but a filing murmur was heard, at a subsequent examination, at the apex of the heart, and accompanying the first sound; also, a murmur preceding the second sound; the first being regarded as a sign of regurgitant disease of the mitral, and the second as regurgitant disease of the aortic valve. The pulse frequent, small, and compressible, and presenting very visible movements. The tongue clean, but red and glazed. Considerable oedema of the lower extremities has existed for the last month.

From these symptoms it was very evident that there was great congestion of the lungs, if not inflammation; and this was the chief object of treatment, the cerebral affection being probably secondary. As he was in a very debilitated state, a small bleeding, to the amount of eight ounces, was all that was ventured on; a blister was applied to the chest, and a rather stimulating expectorant mixture prescribed.

On the 21st the breathing was still more oppressed, and the stupor not diminished; the dulness was now greater over the left than the right side, though considerable in both. The breath-sound was mixed with some crepitation in the left back, and the expectoration was rusty and viscid. The blood which had been drawn was buffed and cupped. As it was evident that now, in addition to the congestion, there was some inflammation, he was cupped between the shoulders, and tartar-emetic was given in half-grain doses. It had been suspected that the symptoms might be connected with disease of the kidneys; and the urine was tested to-day, and found to contain albumen.

On the following day the symptoms were improved; the expectoration presented the same character, and there was still much dulness in the left back, but the crepitation was diminished, and the mind was less op-

pressed. There was still great dyspnoea, and as the expiration was accompanied with a loud wheezing rhonchus, it was expected that there might be some spasmodic contraction of the bronchial tubes, and extract of stramonium was added to mixture to relieve this state.

From this time he improved considerably; the symptoms of cerebral congestion disappeared; the respiration gradually became quite free; the cough continued troublesome, but the expectoration lost its viscosity, was very abundant, and came up readily in large opaque masses. The crepitation was removed, and the dulness of the chest much diminished. The pulse was less frequent and more full; tongue natural. The stramonium was now omitted.

By the beginning of July all the pulmonary symptoms were removed, and the disease of the heart and the pulmonary symptoms alone remained. The antimonial was now omitted, and a tonic mixture, with Tr. Cantharides, was substituted. The albumen gradually disappeared from the urine, which then presented the characters of a simple hydruria, being passed very copiously, (more than double the amount) pale, and of a low sp. gr. The oedema of the feet was very much reduced, though not entirely removed. About the middle of the month he had a slight return of pulmonary congestion, which was soon, however, removed by moderate antiphlogistic treatment. His strength and general health much improved, and he was sufficiently well to be discharged on the 20th of July, the urine retaining the same characters as last described.

It is doubtful, however, how far the cure will prove permanent, as there are still some signs of disease in the lungs, apparently of a tubercular character. There is also a permanent disease of the heart, and there can be little doubt that the kidneys are the seat of granular degeneration, as indicated not only by the appearance of albumen in the urine, but also by the symptoms pointed out in a previous case, viz. the concurrence of oedema with a permanent increase in the amount of urine. The case very much resembles the one preceding it, except that in the former there was a more decided tubercular disease of the lungs in connection with the other affections, by which probably, in both cases, the low inflammation was excited or kept up; but besides this, the morbid state of the blood resulting from the disease of the kidneys would have an injurious influence in this respect.

John Ansley, aged 56, admitted under Dr. Williams, May 29, 1841. A hostler of middle stature, pale complexion, rather spare habit, and good general health.

About a week before admission, while the

weather was hot, his work required unusual exertion, which produced copious perspiration with much thirst, so that he drank much water, and more than his usual allowance of porter, his ordinary beverage.

He felt much weariness and languor, and shortly afterwards observed the scrotum and penis to become distended with fluid, which was followed by oedema of the legs and feet. The urine was scanty and dark coloured, the bowels constipated.

On admission, there was oedema of the legs, scrotum, and penis; no ascites; urine scanty and high coloured, rather turbid, sp. gr. 1030, very slightly acid, rendered whitish and more turbid by the addition of a small quantity of nitric acid, but becoming clear by increasing the quantity of the test; no increased turbidity by the application of heat; no cough; rather more dulness of stroke sound than natural over the heart; sounds of the heart natural, but rather obscure; no signs of pulmonary disease. Pulse slow and compressible, rather full.

The only treatment adopted was the administration of full doses of bitartrate of potash each morning, which produced copious liquid evacuations. The anasarca subsided in a few days; the urine became paler, more copious, losing all traces of albumen, and being considerably reduced in specific gravity, so as to have only that of 1.010 at the time of his dismissal. He was discharged on the 9th of June, ten days after his admission, apparently quite well.

In this case of acute dropsy, the symptoms seem to show that the kidneys were the organs principally affected. Neither the liver nor the heart afford any symptoms of disease, as the increase of dulness over the heart may be sufficiently explained on the supposition that some effusion had taken place into the pericardium, from the same cause which produced dropsy in other parts. The state of the urine sufficiently showed that the functions of the kidney were deranged, there being probably a congested state, which if it had not been removed might have led to the granular degeneration of those organs. The commencing symptoms were very similar to those presented in the case of Yemm previously related, which proceeded much less favourably; in that case, the exciting cause was exposure of the surface to the cold; in this, it was the chilling effects of large draughts of cold liquid applied to the internal surface of the mucous membrane, causing the blood (suddenly increased in quantity by the same potations), to accumulate in other parts; and this having the more injurious influence as acting on a body previously in a state of free perspiration and fatigued by labour.

The curious circumstance of a precipitate,

apparently of albumen, being caused by nitric acid, but not by ebullition, was noticed also in a previous report, and I have likewise observed it subsequently in other instances. The nature of this peculiarity may perhaps be worthy of further inquiry.

The termination of this case is more favourable than that of any other previously reported. Yielding so speedily to treatment, and occurring in a patient who had not before presented any symptoms of disease of the kidneys, the cure may probably be permanent. Had the kidneys taken on an increased action during the operation of the causes which brought on the attack, it might have been entirely avoided; for then the increased amount of fluid introduced into the system might have been safely carried off by those organs, and their tendency to congestion counteracted by their taking on an increased action.

CASE OF BICEPHALOUS MONSTROSITY;

REMOVAL OF ONE OF THE HEADS BY LIGATURE.

I WAS called, on the 31st of October, for the especial purpose of "cutting off a growth from the head of an infant" born the day before. The mother, who had been confined about eighteen hours, was seated at her spinning wheel; the infant was asleep in its cradle. Examined particularly, the head was found small, the forehead flat and ape-like; the face and all other parts of the body natural.

Upon the occiput, and near the posterior fontanelle, there was a large mass, rather larger than the head of the child, appended by means of a pedicle an inch and a half in diameter. This mass exhibited the several features of the face—a cleft for the eye, but without any eye-ball; an elevation in the seat of the nose, and a fold in the place of the mouth. It had no bony cranium, but was composed of a thick scalp, covered with hair, and having a cartilaginous consistence in some places. On the posterior aspect of this cephalic mole there was a spherical mass of a bright red colour, within which distinct fluctuation was apparent. When this red mass was pressed, the infant gave no indications of suffering. When the false head was touched, it cried. When the pedicle was compressed, there were no signs of pain, but symptoms corresponding to those of apoplexia sanguinea were induced, viz. a stasis in the circulation of the part. This led me to believe that the removal of the part with a ligature might with propriety be attempted. I therefore laid open the soft fluctuating part, by an incision two and a half inches long, and gave vent to about five ounces of clear yellowish serum. On sepa-

rating the edges of the incision with a couple of blunt hooks, I obtained a distinct view into the interior of the supernumerary head: there I saw two normally formed hemispheres, with sharply defined convolutions, parted by a deep sulcus, within which lay a firm falciform process.

I now passed a well-waxed ligature or band around the pedicle, and drew the knot with moderate tightness. The infant gave no indication of suffering; it remained perfectly quiet. The ligature was drawn more firmly, upon which the respiration of the child became quickened and forcible; the pulse more frequent, harder, and smaller; the pupils dilated; and the blood-vessels of the head and face injected. The external jugular vein even became apparent through the layer of fat, of considerable thickness, which covered it. I thought it prudent to take a little blood from this vessel. A third pull upon the band completed the ligature, at which moment a stream of blood burst forth from the puncture of the external jugular vein, and three ounces were allowed to flow. The infant was put to the breast, which it took greedily.

The pseudo-cephalic mass was now of a deep livid colour; and a few minutes after the operation was over, it had become quite cold. Laid open longitudinally through the thick scalp, I came upon a regular dura mater, which, besides the falciform process already mentioned, exhibited an imperfect tentorium cerebelli; beneath this a small dark red medullary mass presented itself, which, however, had no similarity in point of structure with the cerebellum: it was without the convolutions and sulci that were apparent on the cerebral lobes; it had no hemispheres, no subdivisions, no crura, no vermiform process. There was no trace of a medulla oblongata. On raising the cerebral mass, I could, however, make out a kind of pons Varolii—a smooth medullary mass, by which the hemispheres of the brain were connected. I perceived no other commissure. The crura cerebri, as well as all the other parts at the base of the brain, were entirely wanting. During the course of this examination the infant was never interrupted in its business of sucking. The parts were covered with a piece of linen dipped in spirits, and the child laid in its cradle. I remained an hour in the house, only quitting it at the distance of three hours after the operation, at which time the infant was tranquilly asleep, and breathing quietly: there seemed every prospect of a happy issue to the case. On my return next day, however, to see my patient, the parents met me at the door, and informed me, with great satisfaction, that God had not persisted in punishing them with the

changeling oaf, for it had just died. Death followed 36 hours after the operation.

The parts were examined anew by Dr. Kersten and M. Loesch. The conclusion was, that the case was one of true, though incomplete bicephalus. The encephalon of the normal head was perfect in all its parts. There was no cerebral connexion between it and the pseudo-cephale; but nervous cords and blood-vessels could be traced into the latter, and processes of the dura mater extended into the connecting pedicle.—Dr. Buehring, in Casper's *Wochenschrift*, No. 1, 1844.

NEW MODE OF PROCEDURE IN OPERATIONS ON THE ROOT OF THE TONGUE.

SURGEONS are all agreed as to the difficulty of removing portions of the base of the tongue; it is almost impossible to succeed with the knife by attacking the organ from the mouth: to say nothing of the narrow space in which the surgeon has to work, the patient is soon choked by the blood that is lost, and there is often nothing for it but to desist, *res infecta*. The chances of better success by attacking the organ from without, between the jaw and the os hyoides, are not much greater: the space is too small, and the parts around the knife are very important. M. Sedillot being required to remove the whole of the left half of the tongue, close down to the epiglottis, on account of a cancerous affection, proceeded in the following manner to this difficult operation.

Having removed the first incisor tooth of the left side, the under lip and the integument of the throat to the level of the os hyoides were incised close to the mesial line, and the soft parts divided; the jaw was next cut through with a fine saw. Two assistants having separated the halves of the lower jaw, the whole of the soft parts connected with the left half were detached down to the level of the velum palati; the tongue was next cleft in the mesial line to its base, and the left diseased portion was removed, the incision circumscribing it at the level of the epiglottis. The whole operation was performed with extreme facility. A ligature was immediately placed upon the lingual artery, and all hemorrhage ceased on the instant.

The two halves of the jaw were approximated and maintained by means of a small plate of gold, secured by a silken thread to the teeth; the lip was united by means of the twisted suture. The patient was so little distressed by the operation that she remained up for some time removing stains of blood, &c.; she had not once felt any sense of suffocation. On the ninth day the lip had completely reunited, and everything promised

a fortunate issue to the case.—*Comptes Rendus*, No. 8, 1844.

HEMORRHOIDS AND THEIR TREATMENT.

M. LISFRANC, in a clinical lecture on this subject, delivered at the Hôpital de la Pitié, directed attention to the extraordinary development of the venous system around the rectum, in contrast with the state of the same system around the vagina, a difference which explains the rapidity with which soothing or simply watery injections are removed from the one passage, and the slowness with which they disappear from the other.

Hemorrhoids, he maintains, have merely many large veins included within them: they do not consist, as is frequently said, of erectile tissue, but merely of a fibrous or dense cellular tissue interlaced with vessels.

It is not always prudent to meddle with hemorrhoids: if the attacks of pain and bleeding be periodical, and not excessively severe, it is better to palliate. The usual French practice, in such cases, is to apply leeches to the anus; but for once that this does good, it many times makes matters worse than they were. M. Lisfranc recommends a bleeding from the arm of xxii. or xxvi. to begin with, and smaller bleedings—three, four, or six ounces—on the following days. Baths, moreover, are useful, and small cool lavements with a few drops of laudanum. The hemorrhoidal tumors ought to be reduced within the bowel, and kept up by means of a compress and bandage.

The extirpation of hemorrhoids is never an operation devoid of danger; and "persuaded," says M. Lisfranc, "that the surgery is a thousand times the most brilliant which cures without shedding blood, I avoid, as much as possible, the knife and scissors in treating hemorrhoids." Regulated diet, gentle exercise, occasional blood-letting, watering-pot douches to the verge of the anus with water at from 60° to 70° F., and now and then the rapid application of the nitrate of silver, so as to stimulate, not to cauterize, succeed in the majority of cases. When the hemorrhoids are ulcerated, he uses the nitrate of silver more freely, or even the acid nitrate of mercury. When the ulcers have a bad character, and the tumors are indurated, it becomes necessary to remove them. Instead of seizing them with the hooked forceps, and removing them at once by one or two actions of the scissors, as is commonly done, M. Lisfranc seizes the tumor with the forceps, and divides the integument around its base by a couple of semi-lunar superficial incisions. He then removes it very gradually, making small snips; and as soon as a vessel is divided that bleeds somewhat freely, he

seizes it, and either ties or twists it. In this way the immediate risk of the operation is lessened; but it is rendered long and painful, and its ulterior consequences—contraction of the orifice of the anus—are not prevented. So far from *Gazette des Hôpitaux*, No. 34, 1844.

[Are our neighbours the French not acquainted with the use of the *confection of black pepper* in hemorrhoidal complaints? The treatment of M. Lisfranc would be still more successful did he employ it; and, as he does not love to shed blood, we feel persuaded that he would keep some in his patients' veins with its assistance, which, without it, he is compelled to abstract.—Ed.]

PRODUCTION OF FAT IN THE ANIMAL BODY.

OUR readers are probably aware how keenly the question of the production of fat has been debated between the chemist of Giesen and the chemists of Paris; Liebig maintaining that the animal body has a certain power of composing this substance for itself out of hydro-carbonaceous articles of aliment; Dumas and Boussingault insisting that the animal composes nothing; that it merely consumes, and depends on the formative faculties of vegetables for all the fat, as well as all the other proximate principles which are found stored up in its tissues. M. Milne Edwards, however, has lately shown that bees fed on pure honey still go on producing wax, a fact which was announced by Huber many years ago; and M. Persoz, from some late experiments on the fattening of geese, finds himself authorised to conclude—

1st. That in the course of fattening, the goose does not merely assimilate the oil or grease contained in its food (maize), but forms a certain quantity of fat at the expence of the starch or sugar of its aliment, perhaps also at the cost of its own substance, inasmuch as the quantity of grease formed is commonly twice as great as that which previously existed in the maize, and the quantity of fat in a fattened goose is relatively greater than the increase of weight which it shows.

2d. That during the fattening the blood of the goose alters sensibly in its composition, becoming richer in fat, whilst the albumen either disappears, or is so much modified that it no longer coagulates with heat or nitric acid.

3d. That there is a certain ratio between the development of the liver and the quantity of fat produced.—*Comptes Rendus*, No. 7, 1844.

OF MOLIERE AND THE DOCTORS, AND THE PRICE HE PAID FOR HIS WANT OF FAITH.

MOLIERE made a butt of physic and physicians. Had he followed the good advice he

received from his medical attendants, however, it would have been better for him,—if longer life be a good. He was recommended to give up playing, inasmuch as the labour was too great for his chest; he was advised to abide by a milk diet, inasmuch as it agreed with him; and he was particularly counselled to live apart from his wife, a heartless coquette, of whom he was nevertheless extremely jealous. He gave no heed to these wise hygienic and moral prescriptions, and died at fifty-one, of an attack of pulmonary apoplexy, which in all human probability might have been warded off for an indefinite length of time, or never have occurred at all.

MODE OF GETTING ON AND OFF IN AMERICA.

IN the north and west (of Alabama?) every village has its old doctor—generally quite a respectable personage, with the regard of the neighbourhood, and the respect of the younger physicians who surround him. A sage of this kind is almost unknown in the south-west. The reason of this difference is three-fold: 1st, a great many physicians die young; 2d, a number go to cotton planting; 3d, not a few marry rich widows. Thus, causes the most opposite conspire to deprive this quarter of the benefits of ripe medical experience. How long the first and second causes may continue to operate we cannot predict, but the third is of a permanent nature; for six or eight times as many husbands as wives die in this region.—*The Western Journal*, Louisville Ky. No. 43.

DISINTERESTEDNESS.

The grape-cure—Die Weintraubenkur, &c. von M. Hirsch.—The author's theory of the good effects of grapes as a principal article of diet would be excellent, *were it proven*. It was certainly a novelty for us to learn, which we do from the author, that those grapes are the best for the grape-cure which yield the worst wine. The spot which the author recommends, as of all others the most favourable for making a trial of the grape-cure is ———, *his own place of residence.*—*From Casper's Wochenschrift*, No. 6, 1844.

THE ROYAL ACADEMY OF SCIENCES OF PARIS.

THE Royal Academy of Sciences of Paris purpose, as the subject of concurrence for one of their prizes of 1845—

To demonstrate by new and searching studies (*une étude nouvelle et approfondie*), and by descriptions accompanied with figures, the organs of reproduction of both sexes in the five classes of vertebrate animals, the analogy of the several parts which con-

stitute these organs, the progress of their degradation, and the grounds upon which a general classification of the reproductive system may be founded (*les bases que peut y trouver la classification générale des espèces de ce type*). The memoirs to reach the Secretary of the Institute's office before the 31st December, 1845.—*Comptes Rendus*, No. 9.

SIR BENJAMIN BRODIE.

At the meeting of the Royal Academy of Sciences of Paris, held on the 18th ultimo, Sir Benjamin Brodie was elected a corresponding member of that illustrious body, replacing the late Sir Astley Cooper, and having 39 votes out of 43.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

List of Gentlemen admitted Members, March 29.—N. B. Gill.—H. Bellinghurst.—T. Philbrick.—T. Nott.—N. Kennicott.—G. F. Moreton.—R. J. Scott.—T. Cochrane.—W. Hoare.—H. Hillier.—A. Mason.—C. Roberts.

APOTHECARIES' HALL.

Gentlemen who have received Certificates, March 28.—C. Barrett, Cortou, Somerset.

CLINICAL
LECTURE ON TETANUS.

Delivered at St. Thomas's Hospital,

By SAMUEL SOLLY, F.R.S.

(For the London Medical Gazette.)

THE subject of tetanus has excited the interest of the profession for many years, and the case which has lately occurred, under my care, in this hospital, is interesting in itself, and affords me a good opportunity of directing your attention to the pathology and treatment of this affection. The disease was known and described by Hippocrates; and, from the severity and intractability of its symptoms, it has been made the subject of frequent mention by many medical writers since. But the most complete treatise on this subject is one written by Mr. Blizard Curling, of the London Hospital, which obtained the Jacksonian prize for 1834. This work will amply repay you for its perusal; it contains a great deal of useful information, and is well written.

CASE.—James Bradon, æt. 42, lighterman, George's Ward, under Mr. Green.—Dec. 28th, 1843, 11 o'clock A.M.—States that his general health has always been good: since the age of nineteen he has been subject to frequent and very severe cramps, which generally come on in the night, and which his wife says have sometimes been so severe as to cause him to get up two or three times for the purpose of seeking relief. These attacks occasionally lasted for three-quarters of an hour.

Although in the habit of freely taking spirituous liquors, it appears that he has not indulged to the extent of intoxication.

Last Monday fortnight, at four in the morning, whilst pushing a barge up Kensington Creek, the little finger of the left hand got jammed between one of the barge

oars and a spike in the leg of a wheel-barrow. This accident gave him great pain at the time: whether there was any hæmorrhage or not he cannot say, as it was very dark at the time.

He continued at his work as lighterman, being often up to his knees in water, taking no notice of the wound beyond applying some "Dutch drops" to it, although at times the arm as well as the finger were very painful. Last Saturday he complained of a stiffness about the neck and body, which was so great as to compel him to give up working.

On Monday he consulted Mr. Statham for what he considered to be rheumatism of the back. He was given a powder, some pills, and a mixture.

On Wednesday his bowels were opened: the motion was copious, dark, and very offensive.

On Thursday his bowels were again opened, but only slightly so, the motion being of the same character as the preceding one. His urine was dark and scanty.

Dec. 28th, 11 A.M.—Mr. Solly was sent for, and in the meantime he was seen by Mr. Travers. On examining the little finger of the left hand, the wound, which was but small in extent, was found to be of a lacerated nature.

An incision was made down to the bone; this was followed by a little bleeding, but no pus escaped. The muscles of the back and neck are rigid and painful; there are exacerbations at intervals of from ten to fifteen minutes, when they are more rigidly painful; the body then resting principally upon the occiput and heels. During these attacks the closed hand can be freely introduced between his back and the bed. He can open his mouth so as to admit the end of the little finger, but with great effort he can separate his jaws to the extent of nearly an inch. He complains of pain beneath the sternum, extending towards the spine. His breath is fetid.

R. Empl. Sinapis epigastrio. Brandy, $\mathfrak{z}\text{iv}$.; Sp. Terebinth. $\mathfrak{z}\text{ij}$. ex Decoct. Avenæ, pro enema. Hyd. Chlor. gr. ij .; Pulv. Opil, gr. ss. 4tis. horis in pulv. Linseed poultice to the finger.

12 A.M.—Was seen by Mr. Solly, who did not alter the plan of treatment.

7 P.M.—Much the same. Has had no motion from the bowels, although at five the turpentine enema was repeated. The face and body are covered with a free perspiration, and the countenance has a peculiarly contracted and wrinkled appearance. He swallows with great difficulty, and complains sorely of his arms being cramped.

8 P.M.—Mr. Solly saw him, and considered the perspiration as a favourable circumstance. Pulse 67, feeble but jerking. To have Enema Mist. Sennæ Co. $\mathfrak{z}\text{ij}$. statim.

10½ P.M.—Mr. Travers saw him, and ordered Ol. Croton. Tiglii, $\mathfrak{m}\text{ij}$. as there has been no motion from the bowels since he was admitted.

29th, 9, 45' A.M.—Seen by Mr. Solly, and ordered—

Enema Tabaci ($\mathfrak{z}\text{j}$. ad lb. j.) dimidia adhibenda statim et repetenda si opus sit.

10, 25' A.M.—About $\mathfrak{z}\text{xx}$. of high coloured urine, having a strong turpentine odour, were drawn off. When examined some time after, it was found to be very thick and of a deep brick-dust colour. Passing the catheter greatly aggravated his spasms.

At 11½ the enema was given him. His pulse was then 74, jerking but feeble.

12½ A.M.—Pulse 62, feeble; has catchings of the diaphragm every two or three respirations, and is covered with a cold clammy perspiration; complains of feeling faint and sick at the stomach. Mr. Travers then saw him, and advised that the enema should not be repeated.

2 P.M.—Mr. South saw him in consultation with Mr. Solly, when the question of amputation of the injured finger was discussed; this, however, was given up, and in its stead two free excisions were made extending to the bone, but no pus followed.

To have Olei Tiglii, $\mathfrak{m}\text{ij}$. statim, repetenda horâ sequent. si opus sit. Beef-tea, arrow-root, wine, $\mathfrak{z}\text{iv}$. Calomel to be continued without the opium.

3, 40'.—Had an injection of gruel.

5.—Had a copious motion of dark green fæces, smelling strongly of turpentine, and very foetid.

8.—Was again seen by Mr. Solly, who ordered a blister to be applied over the whole length of the spine.

To discontinue the calomel, and give instead Træ. Cannabis, $\mathfrak{m}\text{xx}$. every hour till relief is obtained.

Shortly before this visit he had a general

convulsion. Two men attempted, at the patient's request, to set him up in bed, but the spasm produced by this effort was so great that the attempt was given up. The pulse is now as low as 38, and somewhat irregular.

At 10, 15', took $\mathfrak{m}\text{xx}$.; the pulse was then 120. At 11, took $\mathfrak{m}\text{xx}$. of the T. Can.; pulse 110. At 12, was asleep. At a quarter before 1, took $\mathfrak{m}\text{xxx}$. Pulse 144: has had a short nap. At about 2 A.M. had a copious motion of the same character as the previous one. 3 A.M., took $\mathfrak{m}\text{xl}$. When the tincture is taken undiluted, it excites spasm of the muscles of deglutition.

11 A.M.— $\mathfrak{m}\text{xxx}$. At half-past 12, $\mathfrak{m}\text{xxx}$.

At a quarter to 3 P.M. $\mathfrak{m}\text{xxx}$. 4, $\mathfrak{m}\text{xxx}$. 6, $\mathfrak{m}\text{xxx}$. Half-past 7, $\mathfrak{m}\text{xxx}$.

At a quarter to 10, Mr. Solly saw him. The spasms are as frequent, but not quite so severe; has had very little rest during the night; $\mathfrak{m}\text{xx}$. At 11, $\mathfrak{m}\text{xx}$. 12, is asleep.

31st, 10, A.M.—The man complains of great irritation and spasm caused by swallowing the medicine. To be given in the form of enema.

Enema Can. Ind. ($\mathfrak{z}\text{ss}$. ad lbj.) pars 4tis adhibenda statim; repetenda si opus sit.

Half-past 1 P.M.—Has just had his second enema. At half-past 2, a third was given, but it was immediately returned.

3.—In consequence of the enema not being retained, he is to go on with the tincture per ore, in $\mathfrak{m}\text{xxx}$. doses every second hour.

5.—Took $\mathfrak{m}\text{xxx}$. Has just had a severe spasm; complains of aggravation of the pain shooting from beneath the sternum to the spine.

At 7, $\mathfrak{m}\text{xxx}$. At 9, $\mathfrak{m}\text{xxx}$.

10, 20'.—The dose to be reduced to $\mathfrak{m}\text{xx}$. and to be taken every three hours during the night.

Jan. 1st, 1844, half-past 8 A.M.—Has passed a better night than any since he has been in the hospital; but in other respects there is no material change. Has had the Træ. Cannabis in $\mathfrak{m}\text{xx}$. doses at 12, 3, 6, 10, and 1 o'clock.

4 P.M.—His bowels have not been opened since 2 A.M. on the 30th. He is therefore to have Enema Misturæ Sennæ Co. $\mathfrak{z}\text{vj}$. Has taken $\mathfrak{m}\text{xxx}$. of the Tr. C. at 7, 10, 1, 4, and 7, respectively.

2d.—Has had a bad night; complains of having had no sleep, and fancies that a little rest would do him more good than all his medicine. The enema has had no effect.

10 A.M.—As the bowels are still confined, a tobacco enema, ($\mathfrak{z}\text{ss}$. ad $\mathfrak{z}\text{vij}$.), one-fourth to be administered immediately, was ordered; the dose to be repeated if the first

does not cause much prostration. It was no sooner thrown up than it was followed by a free motion from the bowels, of not quite so foetid a character as the previous ones.

To have porter lb. j. daily.

Quarter past 3 P.M.—Had a very severe attack of spasm.

5.—Mr. Solly thinks him much better, and very likely to recover.

To have nothing but nourishment freely during the day. If the spasms increase, the Cannabis must again be had recourse to.

3d.—Is better.

6 P.M.—Is rather flighty, and seems disposed to talk.

4th.—Did not sleep well, on account of being disturbed by the moanings of a patient labouring under compression in the neighbouring ward.

To have Morph. Acet. gr. $\frac{1}{4}$ statim et repetend. 4tis horis si opus sit.

The dose was not repeated, as he slept for about four hours after taking the first.

8 P.M.—Has had some sleep, and feels very much refreshed; his pulse is quiet, and he is in a profuse perspiration.

5th, 11 A.M.—Has passed a pretty good night, and is decidedly improving. If the bowels are not opened by 12, he is to have an Enema Commune.

Rep. Morph. gr. $\frac{1}{4}$.

6th.—Continues improving. The countenance is losing its peculiar wrinkled character, and the neck and back are losing their stiffness. Has spent a good night, and had two free motions, of a lighter colour and healthier character than the former ones.

Had, at 7, an Enema Commune. Morph. at night.

8th.—Has rested well for the last two nights.

Morphia as usual.

9th.—Had a return of the spasms yesterday evening.

To have the blister along spine repeated. The former one has been kept open by means of poultices.

8 P.M.—The spasms are stronger than they have been for the last few days. At their approach the abdominal muscles are tense, and the back a good deal curved.

10th.—Spasms less severe; they come on when any of the students approach and address him.

Mutton-chop, porter, and meat.

11th.—Slept well. The bowels have been opened without the necessity for an enema. Complains of great soreness from the blistered surface.

12th.—Morphia increased to gr. j. o. n.; porter, lb. ij.; brandy, $\frac{3}{4}$ ij.; wine, 3vj.

13th.—Spasms less frequent.

15th.—Has now no spasms. On the 14th, the morphia was omitted, and the consequence was that he rambled during the night.

To have Enema Com. p. r. n.

16th.—Restored well last night. Sat up to-day for about five minutes with no ill effect beyond a slight headache.

17th.—Sat up to-day for ten minutes without inconvenience.

20th.—Instead of the Enema Commune, to have Pil. Aloes co. gr. x.

22d.—Was very much griped by the medicine yesterday, and had tenesmus. The bowels were well opened at 12, after which he was much relieved.

25th.—Going on favourably in every respect; was up yesterday the greater part of the day.

Feb. 3d.—Complains of a stiffness and soreness in the tendons of the hamstring muscles, which oblige him to make use of crutches. Is now quite well.

21st.—The stiffness in the legs is gradually disappearing.

March 5th.—Is to go to-day. Feels quite well. There is yet something about his countenance indicative of pain.

Before we review the particulars of the case before us, let us first consider what is the probable pathological condition which gives rise to these formidable symptoms. A man scratches or wounds his finger; the wound may heal, or it may not; but after a few days a portion of the muscular system is attacked with convulsive action, and shortly afterwards the whole is seized in the same way. The muscles which most frequently are first seized are those of mastication and deglutition; the patient first feeling merely a little stiffness about the neck, but in a short time he finds that he cannot open his mouth; that his jaw, in fact, is locked, in common parlance. The muscles of the back are the next to be affected, and so violently do they contract when the diseased action is severe, that the whole trunk is bent backwards like a bow, patient resting only on his occiput and his heels. This spasmodic action of the muscles is exactly the most unvarying effect of inflammation of the nervous centres of the spinal cord (I do not say that there is no spasm without inflammation of the nervous centres, but I do mean that there is no inflammation of these spinal ganglia without spasm), as I have no doubt most of you are aware. And the conclusion you would arrive at in consideration of the first case of tetanus that presented itself to your notice, would be that the injury to the finger had excited inflam-

mation in the nerve, which extending along the spinal cord had by its action in this structure, excited the tetanic convulsions. Now this, undoubtedly, is sometimes the case, but not, so far as our knowledge goes at present, invariably so.

Many patients have died from tetanus, without their bodies, on a post-mortem examination, exhibiting any marks of inflammation.

Mr. Curling, who has carefully collected and studied all the facts which have been published on the pathology of this disease, and noted many cases for himself, infers:—"That tetanus is a functional disease of the nervous system; that is to say, a disease unaccompanied with any perceptible lesion of structure, the nature of which, although essentially distinct from inflammation, is completely unknown. There are, therefore, no morbid changes peculiar to tetanus, and by which it can be recognised."

The discoveries of Dr. Marshall Hall regarding the excito-motory functions of the nerves and spinal cord, and the localization of those functions in the grey matter of the cord, as a series of ganglia, by Grainger, Newport, and Carpenter, have advanced us a step in the pathology of tetanus. We ought, I consider, to look especially to the cineritious neurine of the cord for the morbid changes upon which the tetanic phenomena depend. I cannot believe that such serious disturbance of the nervous forces can take place without there remaining some change of structure after death, though the means which have hitherto been taken to detect it have not been sufficient for the purpose.

I confess, that my impression is, that tetanus is essentially a local inflammatory disease, and as such should be treated, and that, like all inflammations of the nervous centres, it is accompanied with general want of power. So that while you employ local depletion and counter-irritation, you must also support the system by a nourishing and even stimulating plan of diet.

The success which has attended such a plan of treatment in this case is sufficient to encourage you to adopt it in others, though it would be contrary to past experience to pretend that the favourable issue of the case was positive proof that this result was the effect of the treatment, as it is well known to every practical surgeon that in the chronic form of the disease patients frequently recover, while in the acute they seldom do so.

In reviewing the relative effects of the remedial agents employed, I think it very doubtful whether the Indian hemp had any share in the relief of the symptoms. It is true that the spasms began to abate soon after its administration. But we must not forget that at the same time a blister was applied the whole length of the spine. And

to this agent I am more inclined to attribute the improvement, than to the Indian hemp.

This medicine was commenced on the 29th, but discontinued on the 2d Jan., four days from the date of its commencement, from a belief that the patient was not deriving any benefit from it. The next therapeutic agent employed, the tobacco enema, was decidedly useful in clearing the bowels, if in no other way; and the morphia was of service in procuring sleep, though I doubt whether it exerted any specific effect upon the spasms. You will observe that the patient goes on well to the 9th, still continuing to take the morphia, when there is return of the spasms, with some severity. I then repeated the blister; for the blistered surface, which had been kept open by the linseed meal poultice for some days, had now healed. On the 10th he is better; and on the 18th he is free from spasm, though the morphia was left off on the 14th: which shows that the abatement of the spasms cannot be attributed to its agency.

I am therefore inclined to believe that his life was preserved by the local antiphlogistic action of the blisters, and the support of his powers during the depressing influence of the tetanic spasm, with porter, brandy, meat, &c., and the removal daily of all irritating feculent matter from his alimentary canal.

When this patient was first admitted I seriously considered the propriety of removing the injured finger. I determined, however, in the first instance, to ascertain the condition of the tissues in the neighbourhood of the wound, and to give vent to pus, if any were confined, by a free incision down to the bone. There was not any matter beneath the surface, and the textures which I divided were perfectly healthy; so that, finding no evidence of serious local inflammation and its consequent irritation, I abandoned the idea of amputation. Sir B. Brodie has informed me, that he once put to the test the value of the operation of amputation in the very early stage of tetanus, without any purpose, however, of testing its usefulness. The patient was a boy in whom sloughing of the leg succeeded a compound fracture: it was discovered afterwards that he had exhibited the early and slight symptoms of tetanus on the morning preceding the removal of the limb. It did not arrest the progress of the tetanic disorder, for he died about four and twenty four hours afterwards. On the whole we certainly do not find on record a sufficient number of successful cases in which the operation had been performed for the relief of this disease, to justify us in performing it, when any considerable limb is involved; and even in the case of a finger I should not operate without much consideration.

Considerable importance has been attached to the frequency of the pulse, as an indication of the severity of the disease, and the chance of recovery of the patient. Dr. C. H. Parry even went so far as to say that if, on the fourth or fifth day, the pulse did not exceed 110 in a minute, the probability was that the patient would recover, but if it attained 120 that the chances were very much against him. This opinion has not been borne out by other observers, and, as Mr. Curling has justly observed, the condition of the pulse must be regarded as a very fallacious test of the severity or acuteness of the disease, and cannot therefore be depended upon as a guide in forming an accurate prognosis.

ON THE
DECREASE OF DISEASE THROUGH
THE PROGRESS OF CIVILIZATION.

By C. F. H. MARX, M.D.

Professor of Pathology in the University of
Goettingen.

(For the Medical Gazette.)

WE frequently hear complaints to the effect, that the present times, however rapidly and certainly they advance in a material and intellectual point of view, still fall short physically and morally of what they ought to be; that mankind are weaker and more fragile than they were once; that they are obnoxious to many more dangers now than formerly, and that diseases, in particular, have increased both in number and severity.

There is much that, on a hasty survey, seems to countenance such complaints; in especial, the excessive refinement of manners, and the luxuries which civilization brings in her train; whence effeminacy and debility;—whilst the swelling nomenclature of diseases, and the new and endless variety of means imagined for their cure, are assumed as unquestionable evidence of the fact that matters are even going on with mankind from bad to worse.

Such a view, however, although it may greatly commend itself to us at first, is soon discovered, when fairly put to the proof, to be wholly without foundation. It will, therefore, I believe, be held as neither uninteresting nor unnecessary, if I undertake, by a somewhat circumstantial detail, to show that with the increase and spread

of civilization, the sanatory condition of states and smaller communities has undergone an actual improvement; that diseases, far from augmenting, have rather been falling off in number, and decreasing in intensity; and that every onward step in the path of knowledge and true refinement has had a beneficial influence on the entire corporeal being of mankind.

It is, in fact, not difficult to show that the efforts of science, co-operating with a general humanity of manners, have succeeded not only in eradicating the seeds of many diseases, but even in arresting in the bud such as have come into life; in so circumscribing them, that, finding no congenial soil, they have soon died out, never extending beyond the isolated spot where they sprung.

It is unquestionable indeed, that, with the progress of civilization not only does population in general increase, but that the length of individual life is augmented, whilst the liability to sickness, and the amount of suffering to which every being born may be assumed as obnoxious, are lessened. Epidemical diseases, which, in the olden time, and even in ages not far removed from our own, were regarded as necessary evils, and inseparable from our humanity, are now known within the bounds of truly policed nations by the name alone; and many which were looked upon as punishments for the perversity of the will and spirit, and as hindrances ordained of God in the way of the enjoyment of life, now receive their natural explanation, and meet with their successful remedies. Some of the evils which decimated the race of men still living, and destroyed at once the blessing of sight and the sheen of beauty, approach their end; whilst others that were held as the necessary accompaniments of corporeal and mental development, of arts and of industry, are now known and combated by enlightened theory and experience as strange intruders into the community.

We are perhaps even disposed to believe that a life of perfect freedom—a natural life, as it has been called, spent in tilling the ground, in fishing, in hunting, &c.—must afford the greatest number of hours for undisturbed enjoyment. The walk, the residence in the country, the excursion, which,

with such wonderful certainty and celerity fill the mind with joy, shed such a comfortable sense of well-being over the whole material man, seem of themselves to give us assurance that the intercourse with nature is the secret of health, the panacea for the ills of earthly existence; and that separation from her has sickness and infirmity for its consequence. However true this may be in many respects, it is still indispensably necessary to draw the distinction between that intercourse with nature which is taken as pastime, and for short intervals, and that which is necessary and incessant, and is given as a means of supporting life. The peasant, the fisherman, the hunter, have other tales to tell besides those that are connected with the pleasures and felicities of their several callings. What nature yields must mostly be won with patient endurance or with persevering toil. He who refers himself to her singly and alone, hath indeed room enough for the exercise of his powers; but he hath also a burthen on his shoulders heavy enough to bear.

In the absence of all occupation for the higher faculties, the soul dreams on but too readily in a slumbering or half waking state. But to real, to perfect health, harmony of the corporeal and spiritual aptitudes is indispensable. He who is nothing more than bodily whole, differs but little from the beasts.

The individual, like the kind, has indubitably other duties, other work to do, than by the nearest way to pursue health, and health alone. To secure this inestimable blessing, whilst other objects are attained, is one of the grand purposes of civilization. The cultivation of the higher powers is nowise in itself, and necessarily, coupled with aught that is pernicious. That mental culture is alone injurious to the body, which proceeds without regard to time, or means, or measure. True culture knows best of all what measure is right, what means are proper, what time is fit, and to lay down those rules of being and of doing which fulfil all that is needful to bodily as well as to spiritual health.

The requirements of society, results of our social state, but so often opposed to reason, the omnipotent behests of custom and of fashion, the various springs put into motion by passion and party spirit, are constant causes of a

more passing or more permanent interruption of the sense of well-being; but with a little prudence, firmness, and reason, all of which are legitimate fruits of good education, the prejudicial influences of such circumstances may be greatly diminished, or entirely superseded. In no case are dark and clouded views of the civilized state significant enough to raise doubts of the comfort of its light and sunshine. The impressions made, the knowledge infused, the enlarged views engendered under the mighty influence of social co-operation, of the contemplation of noble works of art, of reading, of oral instruction, and of example, conscious and unconscious,—all arouse the corporeal energies also, and give them play and power. In virtue of the support derived from cultivated intellectual faculties, from acquired force of character and religious submissiveness, man becomes capable of giving ceaseless and successful battle to all the external influences that tend to his detriment. Good sense and moral equilibrium present themselves to us as the means best adapted for achieving elasticity and pliancy under the sorest bodily inflictions. The hardy nurseling of rude nature, without all support from higher sources, sinks, in general, under serious and continued illness, much more certainly and sooner than the tenderly nurtured son of refinement, who, from each achievement of science and art, from intellectual communion through books, from intercourse and conversation with relatives and friends, draws vital refreshment, as it were, from a never-failing spring.

The accounts we have from travellers who have lived long among uncivilized tribes and nations, differ materially in regard to the health and liability to disease of these communities. Whilst some speak of but few diseases as prevalent among them, others assure us that they had there observed the principal maladies to which we ourselves are subject. But when travellers notice few diseases, are we, therefore, certain that these are rarities in fact? Is not the reason rather to be sought for in the inhumanity of the natives, which is in some sort commanded by necessity as it is sanctioned by custom, and the insufficiency of the remedial means with which they are acquainted? They are precisely those diseases which

are most likely to meet the eye that are not seen among savages—chronic dis-temper, slow in their progress, consuming the body by degrees, against which science struggles with might and main, to which she only gives ground inch by inch, or which, more fortunate, she gradually compels to yield, and finally overcomes. Neither are those diseases observed among savage nations, the first symptoms of which neglected or not duly met, hurry the patient rapidly to his grave.

It is well known that fractures of the extremities in our domestic animals do not readily unite, in consequence of the impossibility of keeping them at rest: animals seldom lie, they pass the greater part of their lives standing. Their owners, therefore, rarely risk the trouble and expense of attempting a cure, the completeness and even moderate success of which is always problematical, so that the horse or the ox which breaks his leg is usually put out of the way. But should we, therefore, say that fractures of the bones never occur among our domestic animals?

Tribes and nations which pass their time in war, and have always more or less of difficulty in providing for their wants in the essential article of food, cannot bestow the necessary care upon their sick when affected with lingering diseases. Simple good will is soon exhausted, the instinct of self-preservation prevails over natural affection even for the nearest relative, and in dull indifference, or with some show of sympathy, the victim of disease is by and by left to his fate.

In communities where every one who would be fed must both aid in procuring and deserve his ration, very little care can be taken of those who are affected in their mind, who can do no work, and are only felt as hindrances in the way of every enterprise. The insane are but a kind of corpses, which can only be restored to life through the continued self-sacrifice of the sane who surround them. Left to their fate, and soon sinking under privations from which they cannot escape, they are, of course, more rarely met with among savage or half civilized communities than in civilized societies, where every thing is done for their comfort and maintenance and restoration.

It is also difficult to conceive a life similar to that which we are wont to

regard as having been led by man in his earliest estate, as either peculiarly pleasant in itself or advantageous to health, and when old poets tell us that the first races of men knew nothing of disease,* this is to be taken in the same sense as the assertion that before the fall the earth was without poisonous plants, and the rose without thorns.†

From a much deeper insight into the truth, we find another of the great poets of antiquity‡ ranking it among the benefits which Prometheus, besides the light and warmth of fire, conferred on the first of men, that he taught them physic:—

—When prostrate with disease,
And means were none of cure,—no quickening
drink,
No soothing balm, nothing but death before
them—

’Twas then they learned of me the art to draw
The healing potion from the leaf and root.

To place the influence of civilization on the physical state of man in a true light, however, it is not enough to show that the increase of disease which is presumed to have followed in her train is apparent only; it is easy to do more than this; to prove that a large proportion of the causes of disease with which she has been charged, and which, indeed, are necessarily connected with her, are, nevertheless, diminished in their influence, neutralized, and in many cases made altogether inoperative. The Grecian fable tells us of a lance whose point could wound, indeed, but whose shaft had virtue to heal the wound inflicted.§

One of these causes which has not, perhaps, always been acknowledged, but which must nevertheless be taken as of great importance, is the remarkable fact, that the population of the countries of Europe has long been progressively on

* Hesiod, for example (*Opera et Dies*, v. 90):—

Πρὶν μὲν γὰρ ζῴεσκον ἐπὶ χθονὶ φύλ’ ἀνθρώπων
νόσφιν ἄτερ τῆ κακίῃ, καὶ ἄτερ χαλεποῦ
πύουιο,
Νούσων τ’ ἀραγέλων, αἰτ’ ἀνδρασι γῆρας
ἔδωκαν.

For once there dwelt on earth a race of men
Exempt from evil, from the need of toil,
And eke from each infirmity that brings
Untimely age on us.

§ The lance of Achilles; whence the proverb or
adage ὀτρύνει τὰ σώματα. Vide O. Jahn’s *Telephos*
and *Troilus*. Klet, 1841.

the relative mortality is on the decline.*

It is, however, that if the present rates of mortality are no longer than those that were prevalent among the dangerous periods of infancy and early youth are now carrying out over now than formerly, there is, as it were, a larger margin for disease in general to display itself upon, and particularly for that to which the aged, and even the declining, period of man is liable.†

One, and that an almost inevitable, consequence of the progress of man in the improvement of the mechanical powers, in the extension of the manufacturing system, is the continually increasing multitude of poor labourers, by which the gulph between comfort with respectability and utter destitution is rendered ever the more apparent. Shall not this destitution, this pauperism, of the labouring classes, for which the Saint-Simonians, the Socialists, the Communists, &c. look around them in vain for some remedy, turn out a powerful and finally unmitigable cause of disease? Shall not the habitual use of spirits, which only became common about the begin-

ning of the sixteenth century, the article till then having been reckoned among medicaments, and which is now so frequently abused, not turn out of itself a potent cause, increasing the number of sick in contrast with former times? However certainly this question must be answered in the affirmative, with no less certainty may it be maintained that, along with the apparently inevitable and prejudicial influences of our present social state, the means of meeting and confining them within narrow bounds are developed in like and even in greater proportion.

We even encounter in the higher development of the understanding and moral nature of man, what appears to be a new and powerful cause of disease. The more this is cultivated, the more that is exalted, the more, it seems, are causes accumulated which lead to derangement and disease of the higher organization*. As an assurance that this is so, the fact of the general increase in the number and extent of houses destined for the reception of the unfortunate sufferer under idiocy, delusion, and insanity, might be, and indeed has been, quoted.

A remark of the Stagirate† appears to accord with this, viz. that men who have been distinguished for their talents in philosophy, in politics, in poetry, and other arts, are disposed to melancholy; and also the conclusion of a late Belgian statist,‡ that mankind are more disposed to insanity between forty and fifty years of age, when intellectual works of the highest mark and likelihood are generally produced, than at any other period of life.

A more careful examination of the question shews, however, how insecure and one-sided such conclusions are,

* See Mr Gilbert Blane's *Select Dissertations*, Lond. 1822. He observes that in the year 1822 the population of England had increased sevenfold what it was between the eleventh and fourteenth centuries, threefold from the end of the sixteenth century, and that it had nearly doubled in the course of the last twenty years. The mortality in England, again, appears from Dr. Hawkins' *Medical Statistics* (Lond. 1829), to have been 1:40 in 1790, and 1:58 in 1821; it had, therefore, become about one-third smaller in the course of forty years. In the year 1697 the number of deaths in London amounted to 21,000; a century later, in 1797, despite the vast increase of population, they were but 17,000.

A corresponding ratio is also obvious in other countries, of which somewhat accurately compiled statistical tables exist. In the city of Stuttgart, for instance, according to Dr. Stimmel (On the Population of Stuttgart, Tubing. 1834, in German), the population had increased fourfold in the course of the last two centuries. The number of the births has long considerably surpassed that of the deaths; but this has been the case more particularly in the course of the last twenty-two years.

† Casper informs us that there are accurate bills of mortality extant for the city of Berlin for more than a century, from which it appears that forty-eight per thousand fewer now die in infancy than used to perish eighty years ago, and that twenty-seven per thousand more now reach extreme old age than formerly. See his *Probable Duration of the Life of Man*, Berlin, 1835; and his *Lectures on the same subject*, ib. 1843 (both in German).

‡ In Stuttgart, for example, of one hundred born alive, forty-seven more than formerly now attain their fifteenth year. (See Stemmler on the change in the laws of mortality induced by vaccination, Diss. Inaug. Tubing. 1837, in German.)

* Esquirol, who certainly ought to have a voice in such a question, says (*Ann. d'Hygiène*, Dec. 1830), that advances in civilization increase the frequency of insanity. Idiocy, he holds, may depend on soil, situation, and material influences; but insanity, he says, is frequently in the direct ratio of civilization: it is an effect of social relations, of intellectual and moral influences. In the paper in which he discusses the question: Whether or not there were more maniacs forty years ago than at present (*Mém. de l'Acad. Royale de Médecine*, t. i. 1828), he declares that the increase is no more than apparent. The interest taken in this class of sufferers is now greater than it was formerly. Very poor persons have frequently simulated insanity; and individuals addicted to drinking, who disturb the public tranquillity, are sometimes sent to mad-houses.

† Aristoteles, *Problem XXX.*

‡ Quetelet, *De l'homme*, &c.

and how greatly they who draw them are exposed to error. Much even depends on the meaning attached to words in the inquiry. When the ancients spoke of any one as melancholic, they no more meant to say that he was mentally diseased than we do in ordinary parlance when we make use of the same expression; they rather implied that the individual was disposed to live in self-communion, and abstraction from ordinary affairs, or that he was under the influence of some higher impulse. Genius—decided mental ability in a particular direction—is most rarely in contradiction with itself and overtaken by disease: if it be, however, the case attracts so much attention that it scarcely fails to wax and multiply in the narration that is made of the event.—One man of genius becomes insane, *therefore* genius is prone to insanity; such is the reasoning.

Every man who gets beyond his contemporaries in ingenuity, in ability, in character, is very commonly spoken of as eccentric—perhaps as mad. In historical cases, too, it is always indispensable to inquire into particulars: when it is narrated of the author of the *Jerusalem Delivered* that he was mentally insane, it still remains to be proven that he was so in reality; and then, if he were, to ask what brought him to so sad a pass?

The most richly endowed nature may unquestionably become mentally diseased as well as the most poverty stricken in point of intellect; but in the one it will be regarded as an accident and unusual, in the other as likely and not uncommon.

To regard the culture of the mental powers at large, or of one or more among them, as a ground of their derangement or destruction, is certainly a somewhat hasty procedure. It is not culture, but half culture, that has a pernicious influence upon the mind*. The more numerous and the better the educational institutions of a country are, the less numerous are the insane†. The more the whole of the mental faculties are brought into play, the more certainly will imperfections be set

aside. Inaction occasions derangement still more frequently than activity*.

How rarely do we see men of letters, who labour in peace and due measure, become the subjects of insanity†! It is not, in truth, even intense application of the higher faculties in the noblest ends of life that overthrows the mind, but passion and the changing accidents of fortune, against which, in sooth, elevation of soul supplies the truest remedy. When we see it asserted, therefore, by a late respectable authority‡, that suicide has become more common with the progress of civilization, as it is called, it is a pseudo-civilization that is to blame, not real civilization, which leads us, at an early period of our intercourse with her to know, that the end of life is not mere sensual enjoyment, and that each sore proof to which we are put must be manfully borne.

As an insanity among animals has even been made subject of discussion of late years, and the activity of observers has laid the foundation of a comparative psychiatry§, many might be disposed to search for the cause of the apparent increase of such accidents in the increase of civilization. But we do not see that our domestic animals are now worse fed, or lodged, or accommodated, than formerly; on the contrary their management is better understood than ever it was: and then is it not quite certain that the more general application of purely mechanical forces has long tended, and still tends, continually to lessen the demands made upon animals for extraordinary efforts? If there be increase of psychological disease among animals, therefore, the civilization of man can have nothing to do with it.

Whether the relative number of insane persons is actually greater now than it was in former times cannot be precisely ascertained. The very latest

* According to Louis Raybaud, in Quetelet, op. cit.

† Fuchs, l. c. p. 114.

‡ Bernoulli on Population, Ulm, 1841. Diez (on Suicide, Tubing. 1836), warns us, however, that the assertion of M. Ch. Dupin, "that with the increasing civilization of communities the number of murders or assassinations decreased as certainly and remarkably as that of suicides augmented," is not to be taken, without considerable limitation, for a truth.

§ Pierquin, *De la Folie des Animaux, de ses rapports avec celle de l'homme et les législations actuelles*. Paris, 1836, 2 tom. 8vo.

* See Riecke's Medical Topography of Württemberg, Tubing. 1833; Fuchs's Medical Statistics of Insanity, in *Friedrich's Neue Magazin für Seelenkunde*, Würzb. 1833.

† Fuchs, op. cit. p. 88.

into the same from our establishments the inmates are not altogether unimproved. Even as little as the court-house of an earlier time can be referred to, no category of insane persons, as little as all are now confined as inmates being belong to it. Oxford, the daughter of England's life and is now shut up in Bethlem Hospital, is not insane.

It is not very long since those who were as unfortunate as to be visited with insanity were commonly enough concealed in the private parts of dwelling houses, on various grounds: now, to conceal the family misfortune—the disgrace, as it was held—and again to escape the public interference with relatives, &c. In the present day, insane persons are all but invariably placed in establishments especially destined for their reception, and held under the supervision of the state. These once served merely as places of confinement; every effort has of late years been made to render them places of cure. Formerly, the insane used to be visited, or means taken for their recovery, only when they became alarmingly ill, and towards the end of their disease; now they are placed under treatment from the first dawn of their distemper*. This is one grand cause for the necessity of the larger space and the new establishments which we see devoted, of late years, to the accommodation of the insane; and then, the lunatic, considered as an object of special medical care, is found to require more room than another patient if he would have the best chance given him for recovery: when the object was merely to seclude the madman, very little space sufficed; when humanity insists that the object is to restore him to reason, he must have better entertainment.

Even as little, therefore, as civilization in general can be regarded as the nurse of mental disease, in the same proportion, on the other side, does she step forward as the requirer of the purest humanity in its treatment. Sympathy with man in his affliction, the devotion which, in utter unselfishness, makes sacrifice of itself, never put forth fairer blossoms than do many among our present establishments for the treatment of insanity.

* More than two-thirds of all the recoveries take place in the course of the first year.

The more we advance in our knowledge of this kind of disease, the greater the number of forms which it assumes do we distinguish. But we do not infer from this that the same variety did not obtain in former times. On the contrary, some shapes of mental aberration which we find indicated by our predecessors seem to have disappeared, or to have become ever rarer and rarer in their occurrence. One species of madness, lykanthropy, has ceased entirely, although in the third and fourth centuries, maniacs who roved about at nights in solitary places, and howled in churchyards like wolves, were extant in many countries, and in no inconsiderable numbers*.

Congenital idiocy, particularly cretinism, hitherto held hopeless and irremediable, has nevertheless, in these days, been assailed, and the visitation sought to be made more tolerable by a skilful combination of medical art with the means suggested by enlightened humanity.

The lower animals are often characterised as *dumb*; and there is a certain sympathy with their condition, and pity that they are without the means of intercourse, implied in the expression. But it is only in very recent times that society has shown the least solicitude about those unfortunates among men to whom nature has denied the sense of hearing, and so taken from them the power of developing and using to purpose their organs of speech. The philanthropist and the teacher, however, have now associated them with the physician to inquire into the cause and origin of the privation in each particular case of surdity and mutism, with the special object in view of rendering the state of its subject as endurable as possible, and of enabling him to hold converse with his fellow-men. The deaf and dumb were formerly a heavy burthen on society†. With the exception of a very few, favoured by position and circumstance, who attained to a certain grade of moral and social independence, all the rest—the great majority—were left to their own incapacity, to

* Sprengel, History of Medicine, 3d edit. 2d vol. p. 243.

† Their number is greater than is generally imagined. In the kingdom of Wirtemberg, Riedle (Medical Statistics of Wirtemberg, Tübing. 1834) found 340 deaf and dumb children.

the unmitigated wretchedness of their isolation, in a state of moral and physical degradation, which made them objects not merely of compassion but often of solicitude also. How different at the present time, when, brought up and educated in public institutions especially devoted to the purpose, instructed in reading and writing, their understanding is enlightened, means of communicating with the world around them are supplied, and a substitute is found them for their mute and unavailing organs of hearing and of speech! Let the cause of this abnormal condition of the senses be what it may, civilization very certainly has no portion in it; far otherwise, the sole alleviation for the evil that can be had, comes from her hand.

Even as much may be said of all the establishments for the blind, the deformed, the halt, and the lame, in which science and experience now remove or remedy ills that were certainly as frequent in former times as now, but which were then hopeless burthens to the individual, and sources of charge to the commonwealth.

[To be continued.]

A CASE OF INVERSION OF THE UTERUS:

With Observations.

By T. HERBERT BARKER, Esq.

Member of the Royal College of Surgeons of England, Fellow of the Royal Medical and Chirurgical Society of London, formerly House Surgeon to the University College Hospital, &c.

[Concluded from page 15.]

(For the Medical Gazette.)

FROM what has been written on the spontaneous occurrence of inversion of the uterus, it must be borne in mind that all the sources of irritation which are capable of producing irregular contraction of the uterus should be carefully avoided; such as, on the one hand, hastening the labour; on the other, allowing it to be too tedious; rupturing the membranes too early; alarm and agitation of the mind; the erect position, or leaning forwards over the bed, during labour; the rapid extraction of the body of the child after the head is expelled; pulling at the funis, or hastily extracting the placenta; and all means which are injudiciously had

recourse to in order to increase the power of the pains during labour; such as the free use of stimulants, the imprudent administration of the ergot of rye, or the encouragement of too early bearing-down efforts, which may have a tendency to effect a too rapid, premature, and forcible dilatation of the os uteri, and to produce spasmodic and irregular contraction of the uterus.

After delivery, the uterus should be felt to be in a contracted condition by placing the hand over the pubis, and the binder should not be firmly applied around the abdomen until it has assumed that state under the hand, when it may be cautiously secured; the room should not be over heated, as is too frequently the case; warm drinks and stimulants should then be especially avoided; and the draught of tincture of opium, or other anodyne, should not be administered for at least an hour after the expulsion of the placenta.

If, during the removal of the placenta, the os uteri be felt unusually flaccid, it may be desirable for the fingers to be retained for a time within the vagina, and contraction of this part of the uterus sought to be effected by gentle friction around the inner margin; at the same time guarding against rough pressure over the abdomen.

Hæmorrhage.—Most of our practical obstetric writers state that inversion of the uterus, with partial or complete detachment of the placenta, is accompanied with considerable hæmorrhage; and many of them distinctly assert that death has been speedily produced by the excessive discharge of blood*.

In the case which has been related, the blood flowed more rapidly and profusely than in ordinary cases of flooding, which, perhaps, may be accounted for by the nearness of the bleeding vessels to the orifice of the vagina. Such, indeed, was the volume of blood, and the rapidity with which it was passing away, that I was induced immediately to introduce my hand, and then it was that my fingers came in contact with the inverted uterus, and

* In confirmation of this remark, reference may be made to Dr. Denman (op. cit. pages 420, and 422.) Mr. Newnham (3, 8, 14). Drs. Hopkins (112). Burns (520, 522). Blundell (Lancet, 1827-8, vol. ii. p. 545). The London Practice of Midwifery, edited by Dr. Jewel (310, 311, 312, 315). Dr. Conquest (166, 191, 192). Merriman, (159). Rigby (220). Lee (Clinical Midwifery, 208, and MEDICAL GAZETTE, August 4th, 1843.) Ramsbotham (540, 541) Campbell (492.)

the blood could be felt proceeding directly from the rough surface to which the placenta had been attached. This case strongly confirms, I imagine, the propriety of making an early examination per vaginam in cases of hæmorrhage, in order to ascertain if the uterus have become inverted, as recommended by Dr. Denman, who had occasionally heard of fatal cases from hæmorrhage following inversion—"whether the uterus be inverted or not should therefore in the first instance be ascertained by the methods before mentioned" (by examination above the pubes and per vaginam), "in every case of profuse hæmorrhage after the birth of the child, and particularly after the exclusion of the placenta" (p. 422). By Dr. Hopkins—"we should examine, to ascertain if it be inverted in all cases of hæmorrhage occurring subsequent to labour." (Vol. ii. p. 112.) By Dr. Conquest—"this accident is discovered only by examination through the abdominal parietes, and by the vagina; but should always be suspected, when hæmorrhage, severe pain, and great prostration of the vital powers exist, without the uterus being sensible to the hand above the pubic region" (p. 191). In the *London Practice of Midwifery*,—"sometimes hæmorrhage will take place early after delivery, and whenever it does, we should always examine; there is no difficulty in examining, and it ensures the safety of our patient," (p. 310,) and by Dr. Jewel in his note to this chapter (p. 313.)

It is affirmed by Mr. Newnham, that it has often happened that the death of the patient has taken place from hæmorrhage attendant upon inversion, and the cause has never been discovered, till, on examination post-mortem, the uterus was found inverted in the vagina; and he adds—"in every instance, therefore, after the delivery of the placenta, one or more fingers of the operator should be introduced into the vagina in order to ascertain that the uterus is not inverted. If this simple process were attended to, chronic inversion of the uterus would be known only by description" (p. 8). Regarding, as this author does, the inversion as occurring consentaneously with the expulsion of the placenta, the comparatively indelicate proceeding of formally introducing the fingers after

the removal of the placenta, may be advantageously replaced by the plan which is recommended by Dr. Conquest, of permitting the placenta to slip by one or two fingers of the left hand retained within the vagina.

Opposed to the views of those who consider that the hæmorrhage from inversion is of a dangerous character, is the opinion of Dr. Radford, who regards it as inconceivable, and thinks that it has been much overrated. He states, that in inversion the placenta is generally adherent, and that, if it have been detached from the uterus, this organ contracts as under ordinary circumstances, and the bleeding ceases. If the accident have occurred from pulling at the funis, the placenta in the majority of such cases will be found adherent to the uterus, and necessarily there will be no attendant hæmorrhage; but if the inversion may occur spontaneously, and without the employment of undue force, as we have endeavoured to show, it may, and doubtless in many such cases does, take place after the expulsion of the placenta. I am by no means satisfied that the cases of this disease, from whatever cause they may have arisen, have generally occurred with the placenta adherent. In two of the six cases related by Dr. Radford, it may be inferred that the placenta was expelled antecedently to the inversion of the uterus, and in many other recorded cases the placenta had been previously removed.

If the placenta be entirely detached, and the uterus become subsequently inverted, the body of the organ may undoubtedly contract in volume as in the normal situation, and the hæmorrhage be but slight, but the loss of blood must very materially depend upon the degree of that contraction. If the uterus be contracted but to a slight extent, the vessels remain of considerable calibre, and the bleeding from their open mouths will be profuse. We must not forget, too, the very different condition in which the orifices of the uterine vessels are placed in an inverted, compared with the natural state of the uterus. In the natural condition of the organ, after the expulsion of its contents, the vessels are closed by the equable contraction of its parietes; the margins of the vessels are brought into close approximation, and the flow of blood is thus prevented. In

the inverted uterus, on the contrary, the surface, which in the natural condition is concave, and favourable to perfect closure of the vessels, is rendered convex, and the vessels are made still more gaping. Should there be partial relaxation of the body of the uterus, with or without inversion, the probability of an arrest of the hæmorrhage from coagulation of the blood will be likely to be different in the two cases. In the proper position, the closure of the vessels will be more likely to be effected by the formation of a coagulum, than when the fundus is inverted, placed in a more dependent position, and the mouths of the vessels still more widely opened. The amount of hæmorrhage will, therefore, greatly depend upon the degree of contraction of the fundus and body.

It also occurs to me that the degree of contraction of the os and cervix uteri must exert an influence upon the extent of hæmorrhage. We have seen that the fundus and body, and the cervix and mouth of the inverted uterus, are in different states of contraction in the cases that occur spontaneously. If, after the descent of the fundus and body, the cervix and os uteri continue moderately relaxed, and if the former parts are not strongly contracted, the organ is in a condition highly favourable for the flow of a considerable quantity of blood; but if the os and cervix uteri should take upon themselves to contract firmly, I imagine that such a degree of constriction will be effected as to preclude the possibility of a profuse hæmorrhage. In those cases of inversion of the uterus in which the placenta had been previously expelled, and in which but little hæmorrhage had occurred, it is probable that either the fundus and body were very firmly contracted, or the cervix and os uteri were so constricting the vessels proceeding to the inverted organ, as to prevent the free circulation in the parts below the stricture. On the other hand, where hæmorrhage has occurred to a dangerous and even fatal extent, it is highly probable that all the parts of the uterus, and more particularly the cervix and mouth, have continued more relaxed, and, although the body of the uterus must originally have contracted to a certain extent to have permitted its passage through the brim of the pelvis, it is possible for it

afterwards to become relaxed and flaccid with a very yielding condition of the vagina. This explanation may account for the variable degree of hæmorrhage in the recorded cases, and for the apparent discrepancy between the authors who have been alluded to. In the case which came under my observation, the body of the inverted uterus was not very firmly contracted, and the os and cervix uteri were considerably relaxed, so that the hæmorrhage was profuse.

Constitutional debility may produce that condition of the uterus the most favourable to relaxation after labour; and judging from the temperament of my patient, a general laxity of the system may play an important part in conducing to that condition of the uterine fibre prone to inversion of the organ. My patient had suffered greatly from prolapsus of the rectum, and it is reasonable to infer that the predisposing cause to such derangement of one of the pelvic organs might act as a predisposing cause to the other displacement.

The depression of the system, in inversion of the uterus, may not be proportionate to the loss of blood, and may be extremely dangerous in some cases when the uterus is not speedily reverted, even where but slight hæmorrhage occurs; at the same time it must be borne in mind that this very depression may be one, and no inconsiderable cause, tending to prevent or diminish that loss, by depressing the action of the heart and circulating system.

Treatment. — All writers on midwifery agree in recommending a speedy replacement of the inverted uterus, although, with regard to the propriety of first detaching the placenta in cases where it is adherent, there is some difference of opinion; and as to the precise mode of effecting the reduction, different directions are given by different authors.

Having observed that profuse hæmorrhage is frequently attendant upon inversion of the uterus, it should be an axiom in midwifery, immediately to examine per vaginam in cases of hæmorrhage after the expulsion of the placenta. By attention to this rule, considerable loss of blood may be prevented in those rare cases in which this displacement should occur; and the uterus may be re-inverted with

much greater facility than after the os and cervix shall have assumed a contracted state.

The greater the degree of contraction of the os and cervix uteri, the greater will be the difficulty of reducing the fundus; and as the cervix may become strongly contracted at any period after the inversion has taken place, an effort at reduction should immediately be made. The sooner the attempt is made the more easily will the reduction be accomplished; but we cannot say at what time after the accident it would be impossible to effect it; for some practitioners have succeeded after a considerable period had elapsed. Dr. Denman writes, "The impossibility of replacing it, if not done soon after the accident, has been proved in several cases to which I have been called so early as within four hours; and the difficulty will be increased at the expiration of a longer time. Whenever an opinion is asked, or assistance required, in those cases which may not improperly be called chronic inversions, it is almost of course that the reposition should be attempted; but I have never succeeded in any one instance, though the trials were made with all the force I durst exert, and with whatever skill and ingenuity I possessed; and I remember the same complaint being made by the late Doctors Hunter and Ford; so that the reposition of a uterus which has been long inverted may be concluded to be impossible*."

In other cases it is said that the re-inversion has been effected after several hours, seven or eight days, and, in one case, even twelve weeks, had elapsed†. These cases should therefore induce the practitioner to use every effort at reduction, even where his assistance may have been required at a late period, and to repeat the attempt should his first trial be unsuccessful, rather than regard it as irreducible.

Puzos, Dionis, Merriman, and Radford, recommend that the placenta should be first removed where it still adheres to the uterus; but by other eminent authorities the reduction is recommended to be attempted whilst the placenta is yet adherent. The impossibility of reducing the uterus with the placenta adherent, in some

few cases (see Merriman's Synopsis, page 159), would incline me first to remove the placental mass, should a case of this kind come under my care: nor would the probability of rendering the case complicated with hæmorrhage deter me from this proceeding, since the hæmorrhage would be under direct control, and the greater facility with which the uterus could then be reduced would more than counterbalance the inconvenience from that source.

Mode of reduction.—Two modes of reduction have been laid down in works; the one by grasping the tumor in the hand, and firmly compressing the organ until it shall regain its natural position, as is recommended by Mr. Newnham, Drs. Hopkins (with the hand previously immersed in cold water), Burns, Jewel, Radford, Conquest (with the subsequent injection of cold water), Rigby, Lee, and Campbell; and the other by making an arch or crutch with the back of the fingers, and exerting pressure upon the fundus, as advocated by Drs. Merriman and Ramsbotham, and also by Mr. Newnham (by means of the fingers in a conical form) and Dr. Radford, when the inversion is partial, or merely to a slight degree. Dr. Blundell alludes to both plans of reduction, and states that the one or the other may be desirable according to circumstances; the grasping of the tumor as applicable to the reduction of the completely inverted uterus until it has been thrust within the vagina, and then by pressure upon the fundus or most depending part. In the complete form of the inversion, and when it may have existed for "a few hours, or even perhaps a few days," the mode of proceeding is happily described by Mr. Newnham in the following language. "It is here to be remembered that the cervix uteri is constricted around the neck of the tumor. It is therefore the wisest practice to introduce the hand, and gently grasping the tumor, endeavour to re-invert the uterus by returning first that portion of it which was last expelled from the os uteri. This process will be considerably assisted by pressing upwards the fundus of the uterus, at the same time that we compress gently its superior portion. Here it is, in fact, that the rules for the reduction of strangulated hernia are important, and should never be forgotten. The deli-

* Denman's Introduction, edited by Dr. Waller, page 420.

† Radford's Essay, page 29.

cacy and sensibility of the organ are to be remembered, and all rude and needless irritation should be avoided." (Op. cit. page 16.)

This plan should be adopted in all cases of inversion of the uterus, whether complete or partial: in the former it would seem to be by far the most efficient mode; for, "by compressing the organ, contraction and diminution of its volume will follow, whereby our object will be more easily attained" (Campbell). In the case at the head of these observations, both plans were tried; in the first instance the fingers were formed into an arch, and pressure exerted upon the fundus, which was followed only by a slight doubling within itself of this part of the organ; but afterwards the tumor was grasped within the hand, and by gentle and continued pressure the reduction was speedily accomplished.

After the reduction, the hand should not be withdrawn until the uterus shall have firmly and uniformly contracted. It may be useful very gently to elevate the pelvis, and to keep it in that position by means of some support. The strictest rest should especially be enjoined, and the sitting or erect position prohibited, for a longer period than usual.

Conclusion.—The following deductions may be made from the accompanying case and observations:—

1. That inversion of the uterus may occur spontaneously, and without that degree of force which has been too generally regarded as almost the only cause.

2. That certain circumstances, capable of producing relaxation or irregular contraction of the uterus, are therefore, in every case, to be guarded against.

3. That inversion of the uterus may be accompanied with profuse hæmorrhage.

4. That in all cases of hæmorrhage following the expulsion of the placenta, it should be the first duty of the practitioner to ascertain if it proceed from displacement of the uterus.

5. That re-inversion of the uterus should be attempted as speedily as possible after the discovery of the accident; but that the practitioner should not be deterred from the attempt even after a considerable period had elapsed.

6. That in cases where the placenta is still adherent, that body should be first removed.

7. That the mode of reduction likely to be the most efficient, is by grasping the tumor in the hand, and exerting some degree of pressure upon it, after the manner of reducing a strangulated hernia.

The points concerning which there appears to be considerable discrepancy in the writings of various eminent obstetricians, viz, the possibility of its spontaneous occurrence, and the fact of its being accompanied with dangerous hæmorrhage or not, can only be set at rest by the faithful record and publication of cases occurring in the wide sphere of medical practice throughout the country. The rare occurrence of the disease, and the liveliness with which the main features have been impressed upon my mind, are perhaps a sufficient apology for publishing these imperfect observations. Should they, however, elicit the publication of other cases, or tend to establish more precise rules of treatment, the writer's object will have been attained.

Bedford, March 16th, 1844.

ADHERENT PERICARDIUM.

To the Editor of the Medical Gazette.

SIR,

HAVING observed in the number of your journal of the 29th ult. a communication from Dr. Norman Chevers, in reference to the consequences of adherent pericardium, which appears to have been called forth by some remarks of mine, in a paper published in the 7th Vol. of the Guy's Hospital Reports, and which remarks were repeated in a somewhat different form in the Gulstonian lectures for the present year, I am induced to trouble you with the following observations.

First of all, I would state that I am quite ready to acquit Dr. Chevers of any improper motive in writing that letter, and to concede to him the merit of laborious research for which he so justly contends.

As regards myself, however, it appears to me that Dr. Chevers must have read my paper in the 7th Vol. of the Guy's Hospital Reports very hastily, for in the foot-note at p. 488, of

which he has only quoted the last clause, I said, "It was my intention to have adduced some examples of pericardial adhesion without hypertrophy, had not the subject been well illustrated in the present number, by Dr. Chevers." The meaning of which is, obviously, that the cases were in my possession, and that I had intended to publish them before I received those of Dr. Chevers, and that I withheld them in some measure on that account. The fact was, that it being necessary (in order to keep the size of the number within its usual limits) to suppress some of the matter which was then in my possession, I accordingly, but not I think uncourtously, suppressed my own cases in order to make room for those of Dr. Chevers.

As for the cases which I adduced in the Gulstonian lectures to support the opinion that adherent pericardium does not necessarily give rise to hypertrophy, the case first mentioned was inspected by my friend Mr. T. W. King and myself more than seven years ago, and the fact of old pericardial adhesion without hypertrophy was pointedly noted immediately afterwards by that gentleman, in his account of the inspection, in the records of the Museum at Guy's Hospital; and the last mentioned case was inspected by my friend Dr. Powell, of Tonbridge Wells, and myself, ten years ago, and the same remark inserted by me in my private note-book. Both observations were in fact made long before I had the honour of Dr. Chevers's acquaintance; before, I believe, that gentleman became a pupil at Guy's Hospital. I beg, however, to state, that I do not claim the opinion as originally my own, the truth being that I have heard it, as well as the opposite one, maintained for the last ten years at least, by others, and I may mention, that I remember to have heard the views taken by Dr. Chevers, and partially adopted by myself, maintained at least as long as that time by Mr. T. W. King. I may, too, be allowed to observe, that my opinion has not wholly coincided with that of Dr. Chevers, as expressed in his paper in the 7th Vol. of the Guy's Hospital Reports, for he there rather emphatically states, that the remark that adhesion of the pericardium tends to cause enlargement of the heart "can be applied *only* to one class of cases of this

description—to those in which, super-added to the adhesion of the pericardium, there is also disease of the valvular passages of the heart*," whereas the main object of my second Gulstonian lecture was to point out how and when adhesion of the pericardium *did* produce enlargement of the heart, *without any valvular disease whatever*. Dr. Chevers has, indeed, as appears from his letter to you, somewhat modified his former opinion, but of this I could not then be aware, and therefore could not avail myself of his authority in favour of my views.

Allow me, sir, again to remind you, that I am not now addressing you in order to maintain any claim to originality on my own part, but to set aside an imputation which is implied in Dr. Chevers's letter, and which is of a graver character than that gentleman is perhaps himself aware of, and which I am most ready to believe that his own good sense and gentlemanly feeling will, upon more mature reflection, lead him to regret.—I am, sir,

Your obedient servant,

GEORGE HILARO BARLOW.

7, Union Street, Southwark,
April 3, 1844.

LARGE NEW-BORN INFANT.

To the Editor of the Medical Gazette.

SIR,

SHOULD you deem the following case worthy of insertion in your excellent journal, you will much oblige,

Your obedient servant,

JOHN WHITE, M.D.

Preston, April 1, 1844.

April 1st.—Mary Hyde, æt. 39, residing in Everton Gardens, was this day brought to bed of her thirteenth child. States that her children have always been very large, though she is not much above the ordinary size of women herself. The weight of the present, a female child, is 15 lb. Avoirdupois; the circumference of head is 15½ in.; breadth of shoulders, 8 in.; and length from head to foot, 24½ in. The placenta weighed only 1½ lb.; and the cord is remarkably small. It is by no means an unfrequent occurrence in this neighbourhood to find new-born infants weigh 12, 13, and 14 lb.; and

* Guy's Hospital Reports, p. 421.

the average weight seems to be from 10 to 11 lb.

Notwithstanding the more than ordinary weight of infants at the time of birth, it is worthy of remark, that the generality of adults never reach above the middle size, and by far the greatest number are much below it. It is very probable that this may arise from the early age at which children are sent to work in the factories; and that, although the parent plant be impaired from want of proper culture, it preserves within itself the power of propagating a race which, by due and timely training, might become one of the finest in the kingdom.

CASE OF SUCCESSFUL PERITONEAL SECTION

FOR THE REMOVAL OF
TWO DISEASED OVARIA,
COMPLICATED WITH ASCITES.
By JOHN L. ATLEE, M.D.

PASSING by the account of the symptoms under which the patient suffered for several years, the courses of medicine she underwent, the repeated tapings that were performed, and the large quantities of fluid that were removed from time to time, it was at length discovered that she had in the abdomen two tumors, one on either side, just above the brim of the pelvis, which were referred to the ovaries; and in the absence of any other obvious cause, were held as the immediate occasion of the ascites, which was now rapidly bringing the patient to her end. She was now informed of her real situation, and the one remedy—that of extirpation of the tumors—which would prove effectual. "I frankly informed her," says the author, "of the magnitude, and of all the dangers of the operation; concealing nothing as to its immediate or remote consequences; and detailed to her all the unsuccessful, as well as the successful cases, so far as I could collect them from my own library and those of my friends. I was not then aware of what has been recently accomplished in England by Drs. Clay and Walne; but the triumphant results of American surgery satisfied me that, if my patient, after a full understanding of her case, and the dangers of the

operation, decided upon it, it was my duty to undertake it. With the single exception of L'Aumonier, of Rouen, in 1775, Dr. M'Dowal, of Kentucky, had, so far as the records of medicine inform us, been the first to prove its successful practicability—but few had followed him in this country, and still fewer in Europe. On the contrary, the leading medical and surgical journal in Great Britain had denounced it; had censured those who attempted it; had pronounced it impracticable; and had even questioned the veracity of those who had been the pioneers in this much abused operation. There was, therefore, but little sympathy, and much censure, to be expected, should I fail of success. With my brother only did I counsel in regard to it, and he concurred with me in the propriety of operating.

On the 23d of June, 1843, "I commenced by making an incision about nine inches long, through the skin and cellular tissue, from half an inch below the umbilicus to within an inch and a half of the upper surface of the symphysis pubis. The length of the incision between these two points was owing to the ascitic distension. An opening was now carefully made through the linea alba, a director introduced, and an incision made for an inch each way above and below the opening. Some slight difficulty occurred in doing this exactly in the median line, owing to the adhesions between the parts, occasioned by the previous wounds in tapping. The peritoneum was now exposed, and to test the fact, whether the dropsy were peritoneal or encysted, which had been the subject of discussion between my brother and myself, a very small opening was made through it with the point of the scalpel. This was immediately followed by a discharge of thin and pale straw-coloured serum. Being now satisfied that the dropsy was peritoneal, and had been caused by the obstruction to the circulation, and irritation produced by the tumors, I plunged a trocar through the opening, and drew off about 18lbs. of a similar fluid. The abdominal cavity was then emptied as much as possible, by pressure on its whole anterior surface, and the fascia and peritoneum opened by the probe-pointed bistoury, guided first by the director, and subsequently by

the two first fingers, to the extent of the first incision. About 2lbs. more of serum escaped from the most dependent part of the wound. The first thing that presented itself, when the cavity of the abdomen was opened, was the upper and inner part of the tumor, as large as a goose-egg, composed of very small hydatids, varying from the size of a millet seed to that of a dried pea, and of a cream colour, projecting out of the pelvis on the right side, above the peritoneal investment of the tumor, and overlapping it like a mushroom for half an inch in every direction. Above this, and to the right, was seen that portion of the tumor which projected highest above the brim, covered by peritoneum, and extending over the iliac vessels. In the centre of the pelvis, and very much *in situ*, the fundus uteri could be seen, forming the plane surface previously felt through the integuments, and closely wedged between two ovarian tumors. The left ovary filled completely that side of the cavity of the pelvis, and rose $1\frac{1}{2}$ or 2 inches above the brim, having the fallopian tube and broad ligament expanded over it. The fundus of the vesica urinaria, which had been emptied just before the patient was placed on the table, was close behind the symphysis pubis, and appeared to occupy but little space. The right ovary, on the right side of the hydatid portion, was elevated about four inches above the brim of the pelvis, and was, to my surprise, firmly attached all round the brim and sides, from the crest of the pubis to the projection of the sacrum. From the sulcus formed between the hydatid portion and that covered by the peritoneum, and strongly attached to it, a bright red fillet or band of arteries, about five-eighths of an inch wide and six inches long, and resembling, in regularity of arrangement and size, the texture of a gum-elastic suspender, extended obliquely across the median line of the body, and was attached to the omentum high up in the left hypochondriac region. From the highly injected appearance of the investing membrane of this fillet, I am induced to think that it was the seat of the pain in the above region of the abdomen, so frequently complained of by the patient; which pain had suddenly returned two days before the operation, and still existed at the time of it. As

these arteries, from their size and number, seemed to afford the principal supply of blood to the tumor, a single leather ligature was thrown around the whole, tied firmly, and cut off close to the knot. They were then divided within half an inch of the tumor. I next tried to introduce my fingers between the tumor and the brim of the pelvis, but this was rendered impossible by the firmness of the bands above alluded to. It was now found necessary to extend the incision through the skin, fascia, and peritoneum, down to the symphysis pubis, to facilitate the dissection of the anterior part of the tumor. I then commenced near the crest of the pubis, and by means of the scalpel, probe-pointed bistoury, and the fingers, cautiously separated the adhesions two-thirds of the way round the right side of the pelvis. At this point the bands were particularly firm, and in dividing them a artery of considerable size was cut. This was tied with a leather ligature, and cut off close. It was at this stage of the operation, that in raising a flap of thickened peritoneum, I discovered beneath it the proper, or albugineous coat of the ovarian tumor, and the whole character of the disease was disclosed. In almost all ovarian tumors, we find them covered with a complete peritoneal investment. In this case it appeared, that the inferior portion of the right ovary first became diseased and expanded, and in doing so, after having separated the folds of the peritoneum composing the broad ligament, dipped down into the pelvis, and gradually filled it on the right side. As the tumor increased, it raised up the peritoneum lining that side level to the brim, and there it became firmly attached. But one artery passed into the tumor in that direction. After this was cut and tied, and the peculiar relations of the tumor were exposed, one sweep of the bistoury sufficed to clear it from its posterior connexions, and after breaking up the cellular attachments in the basin of the pelvis with my fingers, I raised the whole out of its bed. That portion of the tumor above the brim, overlapped the iliac artery, and I felt it pulsating strongly when I separated the tumor.

Previous to this time, the small intestines were protruding through the external wound, and interfered with the dissection. Drs. Neff and Parry had

been requested to make pressure upon the sides of the abdomen, with the intention of confining them under the relaxed integuments; but we soon found that this pressure only occasioned a more obstinate protrusion; and during the remainder of the operation, they were easily restrained by my brother, who supported them within the cavity, in the palm of his hand, in the upper angle of the external wound. It was, therefore, unnecessary to use the soft flannel envelopes, wrung out of warm water, previously provided. While engaged in doing this, the extremity of his fingers rested upon the aorta. The benefit of the previous treatment was strongly exemplified in the collapsed appearance of the intestines. They lay flat within the abdomen, and quite free from flatulent distension. Their peritoneal coat was of a pale pink colour, and slightly injected.

So great was the development of this ovarian tumor within the pelvis, and so closely adherent to the uterus, that considerable traction had to be made on one side, while my brother drew the uterus in the opposite direction, before I could pass a common suture needle, armed with a strong double ligature, through the broad ligament between them. The pedicle was then tied very lightly above and below. At the moment of tying the upper one, or that embracing the fallopian tube, the patient complained of considerable pain. Additional force was now necessary to draw the tumor from the ligatures, so as to afford space between them to sever the ligament. It was much thickened and very vascular. The tumor was now removed on the right side. That formed by the left ovary next required attention, and occasioned but little difficulty. It was covered throughout by peritoneum, and was unadherent, except by its natural attachment. As before stated, it filled up completely the left side of the cavity of the pelvis, the uterus being jammed closely between the two. It rose about two inches above the brim. Passing the fingers of the right hand between the side of the pelvis and the tumor, it was readily slipped from its bed, and given to held by the assistant. Another needle, armed with a double silk ligature, was then passed as before, and tied above and below. The patient complained of similar pain when the left fallopian tube was tied. The broad

ligament was now divided and the tumor removed. The uterus, free from disease, remained standing upright in the pelvis, and shorn of its natural attachments. The cavity of the pelvis, which contained some blood and more serum (for very little hæmorrhage attended the operation), was now quickly cleansed by a succession of *very soft* sponges, rapidly handed to me by careful assistants. This I considered preferable to turning her upon her face, as was done in some previous operations, for the purpose of evacuating the fluids. Deeming it most advisable to remove the leather ligature around the omental arteries, as my leather ligatures had not been satisfactorily prepared, I did so, and replaced it by a silk one; one end of it was cut off close, and the other brought out at the lower orifice of the wound. No hæmorrhage followed the removal of the ligature, and on squeezing the extremity of the fillet of arteries, several circular coagula escaped from their mouths. The edges of the whole external wound were now carefully approximated and secured by seven *hare-lip* sutures—separated about an inch from each other.

Within a month, the patient, who had done perfectly well from the first, was up, and Dr. Atlee discontinued his regular visits. She recovered completely. In concluding his report of the case Dr. Atlee says:—

I cannot avoid remarking that it will scarcely be believed, that an incision between ten and eleven inches long could be made through the walls of the abdomen; the viscera exposed for half an hour; the intestines protruding for a portion of that time; the peritoneum extensively divided around the whole right side of the brim of the pelvis; both broad ligaments and fallopian tubes be severed from the uterus; six ligatures applied, and the cavity sponged; and yet, that no symptoms should arise to create apprehension or embarrassment. Yet such it will be perceived was the fact, incredible as it may appear, and I dwell upon it with hope that it will present to the profession an inducement hereafter (added to the testimony already before us) to make a similar effort under similar circumstances. No one can be more disposed than myself to condemn the rash or wanton use of the knife which we frequently see exhibited. True surgery would seek to banish it."

possible, from the list of remedies; and by a faithful application of such means as observation and experience have proved capable of exerting an influence upon the various functions of the body, endeavour to control its morbid states, and restore its primitive integrity. Unhappily this is not possible; our means are still too limited; resort must be had to the knife, and the case above detailed proves its efficiency and safety.*

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALBERT.

The Principal Offices of the Brain and other Centres. By JOSEPH SWAN. 8vo. pp. 31. Longman and Co.

MR. SWAN has achieved an honourable reputation for himself as an anatomist. His "Demonstration of the Nerves of the Human Body," and his "Illustrations of the Comparative Anatomy of the Nervous System," are not only creditable to his dexterity as a dissector, but to his spirit as an author; for it is generally understood that these works are produced at the sole cost of Mr. Swan himself.

In the unpretending publication before us, we have the pleasure of meeting Mr. Swan as a physiologist. We can believe that the change from the regions of certainty—of simple physical quality, form, dimension, connection, &c. &c.—to those of speculation, cannot have been very agreeable to so pains-taking an observer as our author. And who shall say that the entire physiology of the nervous system is not yet to create—is not a kind of dream? Anatomy, however, if it will not reveal to us the office of any individual part—which it certainly will not—may still usefully serve us as a guide in our endeavours to discover function; there must at all events be harmony between structure and function. It is therefore with sincere pleasure that we greet the lucubrations of so accomplished an anatomist as Mr. Swan in the difficult department of physiological science which he has selected.

In a brief introduction he contrasts animals with plants, and shows what is necessary in regard to constitution or

structure to each for the performance of its faculties. The nervous element is the seat of the SENSORY; and when this is aggregated into centres and nerves, it is fitted for receiving the soul—the Psyche.

SENSATION he defines to be a stimulus or impulse from mechanical or chemical agents on peculiarly formed external organs, and directed to centres specially constructed for receiving different kinds of them, and conveying them to the sensory. The quality of sensation is high according to the extent of the convolutions of the brain in proportion to the medulla oblongata; and a large brain requires and tends to maintain a high state of respiration. We were not prepared for the conclusion that where the intellectual faculties are to be much exerted, the respiration will be increased. The man of letters and the student surely consume less oxygen than the coal-heaver and the ditcher. Neither should we have imagined that the lungs of birds were small in proportion to their brain (p. 9.) The high temperature and rapid consumption of oxygen by birds, we had always held as synonymous with a largely developed pulmonic system.

PERCEPTION is defined to be an impression made on the nervous system, of which the animal is unconscious.

The cerebellum Mr. Swan does not agree in considering, with the French anatomists, as the part which regulates or co-ordinates motion. It is much rather an appendage of the brain, he says, than of the medulla oblongata and spinal cord, the acknowledged seats of the motory power. It does not correspond with the number and size of the sensitive and motive nerves; it is not required for the intellect, the special senses, common sensation, or volition; nor is it concerned in digestion or assimilation; and is not proportioned to the heart, lungs, chest, or any organ, nor yet to the reproductive faculty generally, although it must be confessed that this faculty is very active in the porpoise, where the cerebellum is very large (p. 11.) We rather think that Gall was right in his estimate of the function of this part after all. But we must refer those of our readers who take an interest in the physiology of the nervous system to the modest pamphlet itself, where they will find much valuable information in very brief space.

* American Journal of Medical Sciences January 1844.

An Account of Sir Charles Bell's Classification of the Nervous System. By ALEXANDER SHAW. Royal 8vo. pp. 30.

WERE we ambitious of being held in green remembrance among our contemporaries, and successors on the theatre of life, when we are dead, we should desire no more loving, or true, or persevering proclaimer of our deserts, than Alexander Shaw. Sir Charles Bell is his cynosure, his polar star, and he will not be satisfied unless we all consent to steer by that light, and to revere that name with a reverence equal to his own; to appreciate Sir Charles's discoveries even as he their faithful chronicler appreciates them. There is, however, something beautiful in the child-like devotion, the boundless admiration, with which Mr. Shaw evidently keeps his gifted kinsman in his mind's eye. It is of the same nature as that wherewith John Abernethy used to cherish the memory of John Hunter, and to coin the views and opinions he delighted in himself out of the love he bore the mighty name. We would not disturb Mr. Shaw in his admiration of Sir Charles Bell, but we seriously opine that Sir Charles's presence in the world has already had its effect; and that the arena may now be safely left to the men who have succeeded him, pigmies for the most part, it may be, in Mr. Shaw's estimation, to him, but yet possessed of all that Sir Charles knew, and something which Sir Charles did not know. *He was a great man*, and whoever speaks of the structure and functions of the nervous system through all the generations of men that are yet to come, if lamp-black in oil impressed on old rags hold good, must quote his name. Let this suffice Mr. Shaw, and we trust we shall now find him turning his powers to the advancement of science on his own account, which he is extremely capable of doing.

The work before us is intended as an appendix to the third edition of Sir C. Bell's work, "*The Anatomy of Expression*," recently published, and is in fact another account of Sir Charles's mode of procedure, and of the results at which he arrived. It must be interesting to the laity, who are altogether unacquainted with the anatomy and physiology of the nervous system, but contains nothing that the professional

reader will find new. It is nevertheless apparently a necessary supplement to the book on *Expression*.

MEDICAL GAZETTE.

Friday, April 12, 1844.

"*Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.*"

CICERO.

THE POSTHUMOUS FAME OF MEDICAL MEN.

WE all know what gods we are in the eyes of our patients—when they are seriously ill; how little they think of us, with what slender courtesy they treat us—when they have got quite well. The eagerly expected visit, the confidence in, the dependence on us, are not more remarkable in the first case, than are in general the indifference, the coldness, the want of sympathy with us in the second. The truth is, that the wealthy and the great are generally afraid of the accomplished and philosophical physician or surgeon, intimately acquainted with the springs and motives of human action as he necessarily is. They have a higher nature in their presence, which over-crowds them; and human pride and human infirmity cannot stand the proof; they shrink before it, and rather dislike and fear, than love it. This feeling is at the bottom of the preference which the aristocracy of all countries, and of England in especial, so frequently show for ignorance and blind empiricism—for the anointings of a St. John Long, the abracadabra of the druggist Hahnemann, the duckings of the peasant Priesnitz, &c. &c.

With the same measure that the world are disposed to mete to us during our lives, do they still continue to measure to us after our deaths. The fame of the medical man is not even so enduring as that of the great actor. By

what strong memorial do the public cherish the remembrance of the gifted Abernethy? They name a biscuit after him. Of the brilliant Cooper? some speculative druggist has christened a pill by his name. Of the great Dupuytren? a perfumer embalms his public memory with a pomatum for the hair! Sic transit gloria! Mr. Abernethy always estimated posthumous fame at what it is probably truly worth, and no more: "Were I thirsty," he would say, "I would give the posthumous fame of Buonaparte, could I command it, for a drink of small beer!" Brave old John, kind-hearted, eccentric old man! Nor shall thy fame for better things than biscuits yet die out from amongst us thy brethren, for some considerable time to come! Though thy kindred wrote trash upon thy tomb-stone, and the bakers have kneaded thee up with their dough, the influence thou hadst on medicine will survive when the memory and the knowledge of thy being shall have passed away!

And this brings us to the point we were driving at. There is no sure abiding place for us here below—whether in the body, or in that kind of spirituality which we entitle posthumous fame. He who did this or that passes away; the knowledge of him who did it is lost in the night of ages; but the deed itself, the thing done, remains, and has its influence to the end of time.

Our business, therefore, is honestly and pains-takingly to perform the part assigned us, without regard to our particular fame, satisfied that what we do for good will never be lost to our fellow men, and that though we neither leave our name to a biscuit like John Abernethy, to a vegetable pill like Sir Astley Cooper, to a sauce like Dr. Kitchiner, or to a pomatum for the hair like the Baron Dupuytren, our spirit will still be present in the world

when the body that enshrouded it is resolved into ashes and air, and all knowledge that such a man had ever been has passed away.

VENTILATION OF THE ROYAL MEDICAL & CHIRURGICAL SOCIETY.

WE venture very humbly to suggest to the Council of this Society, that the room, in point of ventilation, is a disgrace to them, who govern, and to the Fellows at large, who submit to such misgovernment. If we be too numerous a body, and the object be to get rid of a certain number of us by suffocation, let the purpose be made known, a' God's name, and we shall come to the Society knowing what is intended for our entertainment. We venture to suggest the addition of *sulphur fumes* to the already delectable atmosphere of the place. A penny or twopence spent in *brimstone* each night of assembling, would be money well and pleasantly laid out, and the thing only wants this to be made quite perfect. We, however, are neither Shadrach, Meshach, nor Abednego, and must positively decline being put into any such fiery furnace as the room of the Royal Medical and Chirurgical Society, for the future. How those poor gentlemen, the secretaries, find breath for their duties we can scarcely understand; it must be "the strong will," "the indomitable courage,"—such as possessed Milton's heroes in Pandemonium—that carries them through; and as to Mr. Hancock and Mr. Lloyd, and the other voluntary speakers in ordinary to the Society, how they muster resolution to make such an effort as talking needs must be in such an atmosphere, we are totally at a loss to comprehend: it must be a very powerful motive indeed that induces so desperate an effort.

Let the president, vice-presidents, and council, turn forthwith to some elementary book on physiology—Mr. Williams may bring them in Bostock or Müller at their next meeting, and refresh their memories with the facts—they must have forgotten them—that man requires from ten to thirteen cubical inches of *atmospherical air* for each respiration, and that he makes from fifteen to sixteen such respirations

in a minute. We must have made at least twenty-five the last time we were there, but our lungs seemed disposed to do with as small a quantity of the "congregation of pestilential vapours" as possible, and we probably did not consume more than eight or nine cubic inches at each inhalation; but say the quantity was ten cubic inches, and the respirations fifteen: $10 \times 15 = 150$ cubic inches per man, per minute; $150 \times 60 = 9,000$ cubic inches, or 3,000 cubic feet per man, per hour; $3,000 \times 1\frac{1}{2}$ hours, the length of the meeting, $= 4,500$ cubic feet per head; taking the number present at 100, this would give a consumption of 675,000 cubic feet of air for the hour and a half during which the meeting lasted; but the Society's room is not more than a cube of about 35 feet in the side, and consequently contains no more than 42,875 cubic feet of air; it would therefore require to be totally renewed at least fifteen times during the time of the meeting, in order to be kept sweet and wholesome. Let Dr. Arnott, or Dr. Reid, be forthwith entreated, in sheer humanity and brotherly professional regard, to tell the council how they would proceed to secure the needful supply of air to 100 wretches confined for one hour and a half in the black hole of Calcutta; and if they use the means suggested for this extreme case, they will exactly hit the exigencies of the room in Berners Street. If they do not get such information, and act on it, against next meeting, we trust they will be ready with the brimstone.

NERVES OF THE GRAVID UTERUS.

FROM the following corrigendum inserted at the end of Dr. Lee's lectures, it now appears that Dr. Hunter never examined the nerves of the gravid uterus. "In the first lecture, at page 11, it is stated that 'Dr. W. Hunter was the first who distinctly traced the great sympathetic and sacral nerves into the uterus, and suspected that the nerves enlarged during pregnancy. As he never examined the nerves of the unimpregnated uterus, and saw the nerves of the gravid uterus dissected only in one subject, he could not possibly assert that they increased after conception.' And in Lecture XI. at page 98, it is re-stated that 'Dr. William Hunter

was the first who examined the nerves of the gravid uterus, and suspected them to be enlarged in proportion to the vessels.' A learned and ingenuous friend has called my attention to Dr. Hunter's own words, which are as follows, and which certainly do not bear the interpretation I have put upon them:—'*I cannot take upon me to say what change happens to the system of the uterine nerves from utero-gestation, but I suspect them to be enlarged in proportion as the vessels are.* Upon this occasion we profess only to give the anatomy of the gravid uterus; yet since the descriptions of the nerves of the uterus which I have read seem to me unsatisfactory, I shall so far go beyond my subject as to describe the hypogastric nerves, such as they appeared to me in a female subject carefully dissected for that purpose.'

"It is now obvious that I had misunderstood altogether the meaning of this passage, and supposed that Dr. Hunter had examined the nerves of the gravid uterus, when he referred merely to a dissection of the nerves of the unimpregnated uterus. No injustice to Dr. Hunter has resulted from this mistake; but it is not improbable that a recent editor of Dr. Hunter's work on the gravid uterus has been led by it to commit the following egregious error. "Indeed, when we carefully peruse the last paragraph of Dr. Hunter's chapter on this subject, (which is quoted verbatim Lecture XI. page 100), we cannot help coming to the conclusion, that it still contains the chief, if not all, of what we know for certain about the nerves of the gravid uterus.'"

DISPENSARIES FOR THE RELIEF OF THE SICK POOR*.

It seems that some time ago there was a considerable feud among the governors themselves, and then between the governors and the medical officers of the Brighton Dispensary. On the foundation of that establishment, the medical staff consisted of two physicians and two surgeons; and so it continued, until from circumstances, a temporary difficulty was experienced in procuring the services of physicians [when could that have been, where was duty to be done for nothing!]

* A Letter to the Governors of the Brighton Dispensary, On the Constitution of Dispersaries for the Relief of the Sick Poor, by a Medical Practitioner. Brighton: R. King.

when the staff was reduced to three surgeons or general practitioners. This reduced number of medical officers has been permitted to continue in charge of the Dispensary, although the number of applicants for relief has increased to nearly double that which it was a few years ago, when there was not only a larger but a differently constituted medical staff to attend upon them; and so disproportionate have the demand for assistance and the means of supplying it become, that it is calculated each surgeon sees forty patients on the day of his attendance at the Dispensary.

It was proposed, on account of this great increase in the applications for relief, to double the number of medical attendants; and to appoint physicians as well as surgeons to the Dispensary. By such an arrangement also, it was supposed that the cases of those who were too unwell to attend at the Dispensary, but who must be visited at their own houses, could be placed under the care of the different senior medical officers, instead of being left, as at present, to that of the "house surgeon," who, it may be presumed, however talented and diligent, cannot usually have had the experience of the "ordinary" medical attendants; and who has other important duties to perform at the Dispensary, almost incompatible with that of making fifty or sixty visits a day upon the sick at their own dwellings.

These reasonable propositions, however, were twice rejected by a majority of the few governors who usually attend the general or special meetings, on the grounds, as it was said, that the poor had not complained of the present arrangements; and that the medical officers now in charge had not sought assistance or declared their inability to attend properly to the greatly increased number of cases. These are the circumstances which have called forth the clever letter of the Medical Practitioner, in which there are too many good things to be lost. Some of these we take it upon us to impart to our readers.

"But how," proceeds the letter-writer, "is it possible that the cases of forty patients, a great proportion of which come before the medical attendant for the first time, can be properly investigated in one day, and notes taken of the important circumstances of each for subsequent reference during the treatment, by a surgeon whose subsistence depends upon other laborious occupations, and much of whose time must be devoted to reading and study, in order to keep pace with the rapidly progressing science of his profession?"

But slight affections, it may be said, and the majority of applicants at the Dispensary complain only of these, do not require so much care. There cannot be a greater mis-

take. As far as regards internal disease, these slight affections are generally such as it is most difficult to ascertain the nature of, and often also, as respects the treatment, the most important. It is easy to detect great organic change; but it is too frequently only in the beginning of disease, and before disorganization has taken place, that medicine can much avail. If this opportunity be lost, the patient's life may be rapidly brought to a close, or become a wearisome burden to himself. No fact is better established than that the greater number of diseases become severe or incurable from neglect or improper treatment on the part of the patients themselves, or the practitioners whom they consult, in their incipient or early stages.

To detect the seeds of disease only beginning to germinate, and to eradicate or destroy them before the constitution is fatally vitiated by their presence, is a task difficult to the most talented and the best informed. The nicest discrimination is often necessary between the disease itself and those merely sympathetic disturbances occasioned by it, in order that remedies may be applied to the real source of the evil. In private practice, the care and attention required for such discrimination is commonly given. The practitioner's reputation and interest are here too much at stake to admit of superficial inquiries, unless his *fashion* be a substitute for every important qualification. Few medical men can dare to appear satisfied with an enumeration of the general symptoms, where percussion and auscultation are applicable, and without frequent inspection, and sometimes chemical examination, of the secretions. The interest of the practitioner is generally the safeguard of the patient in private life; but how are matters carried on at public institutions? If a practitioner overburdened with private practice cannot bestow the requisite degree of attention on the cases of those who consult him, he has at least a plausible, though far from sufficient apology, in the consideration that his patients, being generally well-informed people, must be sensible of this as well as himself, and that their employment of him to *guess* at their diseases is perfectly optional. But it is otherwise at public institutions: the poor who apply there have no choice; and, consequently, the practitioner who undertakes their cases has no excuse for carelessness or neglect.

Nor is it that there is any difficulty in procuring the services of a sufficient number of properly qualified medical officers for these charitable institutions. Those attached to them, indeed, are often notoriously (from the defective mode of election) not always the most able; and there would generally be applicants of at least equal talent and

character, for three times the number of offices. But the distinction to the medical officer in possession would then be less, the prize would not then be so valuable; and society is not generally aware that the men who are most eager for such prizes and distinctions are not always those whom it is most for its interest to foster. Inquirers into science for its own sake, seek every opportunity for its cultivation regardless of such advantages; but they are too often unfitted, by the constitution of their minds, to submit to all that is necessary for successful competition.

After these observations upon the necessity of increasing the number of medical officers of the dispensary, the Medical Practitioner proceeds to point out the advantage that would arise from part of these being physicians, and part surgeons, which he defends on the principle of division of labour. The Court of the Society of Apothecaries, in a circular respecting dispensaries as medical schools, issued a few years ago, ordain that "no dispensary will be recognised by them as a school of practical medicine which (if within the limits of the jurisdiction of the College of Physicians of London) is not under the medical care of *at least* two physicians, each of whom is a fellow or licentiate of the said College; and if beyond these limits, that is not under the care of *at least* two physicians, who, if not so qualified, are graduated doctors of medicine of a British university, of four years' standing." (*MEDICAL GAZETTE*, vol. xi. p. 671.)

If the proper number of physicians could not, at any future time, be obtained for the Brighton Dispensary, the deficiency could be supplied by an increase in the number of the surgeons; and if the nomination of either were left to the judgment of a small body of the governors, competent, from their education and other circumstances, to make a proper choice, it would be a vast improvement on the existing system of election. At present, the man who starts first in the race, or who runs fastest, is the most likely to succeed, provided that each has an equal proportion of bronze in his composition, to enable him to urge his requests with sufficient importunity, and to bear patiently with the contumelies of his canvass.

After these remarks on the advantages of increasing the number of medical officers, and appointing men of different departments of the profession, our Practitioner proceeds to answer the objections that have been made to these proposed alterations.

No complaint, it is alleged, has been made by the poor against the present arrangement. Whether this be the case or not, I have no means of ascertaining. But granting that

no complaint has been made, what would this signify? Are the poor competent judges of the degree of attention which their cases may require, or of the capability of those who attend them? Nay, their confidence in the medical man's skill may sometimes be in an inverse ratio to the time he expends in investigating their diseases. How clever, they may think, (and wiser persons than most of the poor, occasionally commit the same mistake) must this man be to discover at a glance the nature of our maladies! The poor are only fastidious about the medicine which they receive; if this be abundant, they care very little whether he or she who prescribes it has become initiated in the art of prescribing by long-continued observation and study of medical facts, and the perusal of ancient and modern medical writers of celebrity; or by consulting for receipts to cure, as a cookery-book is consulted for receipts in cookery, forgetting Mrs. Glasse's directions, "First catch the fowl," *i. e.* First establish the diagnosis, &c. There are bountiful dispensers of medicine of the latter class at Brighton, who enjoy a reputation for skill which the "regularly bred" may well be envious of. And if a minute or two is all the time that is dedicated to the consideration of their cases, the poor can scarcely avoid coming to the conclusion that the choice of medicine, or its appropriate exhibition, is a matter of minor importance.

Yet variety of physic, to a certain extent, is looked for by the poor, as well as abundance. The writer was told by a gentleman connected with the Poor-Law Commission, that only one of the thousand Union surgeons in the country (elected by the lowest tender, and consequently not all necessarily luminaries of the brightest lustre) had been dismissed from his office, on a complaint of the poor affecting his professional character. They received *plenty* of medicine from him, they said; they had no complaint to make against its quantity; but they could not understand the reason, various as their diseases were, of their being all supplied, without distinction, out of *one* bottle.* Yet this

* In *Lancet*, Nov. 25, 1843, will be found an account of another dismissal of a medical officer by the Poor-Law Commissioners. In this instance the complaint was not against the quality but against the *quantity* of the medicine. This surgeon is dismissed for treating his patients *homœopathically*, which must be quite as distasteful to them as the "one bottle" system. The conduct of the Poor-Law Commissioners in this proceeding is unobjectionable. If the rich and well-informed choose, in spite of common sense, to be treated *homœopathically* or *hydropathically*, there is no help for it; but the poor have no choice in the matter. As regards those who prefer being so treated, it is much to be regretted that the hazardous experiments which they are willing to make, and for which their fellow men ought to be much obliged, should fail in effecting all the benefit which they are otherwise ~~able to~~ ^{able to} produce, from the want of adequate observation

licensed destroyer, had he given them due variety as well as abundance of physic, would, probably, on account of this being free from cost, have been preferred by the poor to the most distinguished practitioner not having the power of ordering them medicines gratis.—An apothecary, some time since, became the oracle of his neighbourhood by studying the tastes of his customers as regarded quantity and quality of physic, as well as by an ingenious mode of appropriating his drugs to their several ailments. Standing behind the counter with grave demeanor, and holding a large empty phial in his hand, he commenced his examination of the patient, and continued pouring into the phial at intervals, as the examination proceeded, a little of the contents of the various bottles on his shelves, according to the enumeration of the various symptoms, until the list was finished, or the phial was full; each addition, receiving, of course, the character of being a specific for the particular pain, sickness, or weakness described. A little incongruity was of no moment in the composition of this medical shrapnell; one part of the mixture might have been pronounced a refrigerative for the hot stage of the patient's fever, and another, a cordial for the cold stage; part may have been intended to dispel his drowsiness in the day, and part to remove his sleeplessness at night.

I doubt very much whether an intelligent practitioner condemning the pernicious system of pouring "doctors' stuff" into the throats of all who apply for relief (a system adopted by certain alumni of the mechanical school, who wish at once to expel the disease by their substantial administrations, and prevent its return by filling up every vacant space), and limiting his prescriptions, in appropriate cases, to little more than regimen, would not be complained of by the poor, as depriving them of what they considered essential to their cure; while their praise would be awarded to the blockhead who is ignorant that, although it is professional and classical to stuff an alligator, it would often be as bad practice to stuff a patient as to shake one. And yet we are told that the satisfaction or dissatisfaction of the poor with the system in question is to be the criterion of its eligibility!

Are the richer and better informed classes always competent to form a correct opinion

of the merits and capabilities of their medical attendants, or of their habits and modes of practice? Are they themselves always proof against the various tricks of self-eulogium and rival-depreciation, of hypocrisy and cant? Do not we, every day, hear the moral and medical excellencies of ignorant pretenders to medical science, whether licensed or unlicensed, trumpeted forth by persons who, in all other things, evince sound judgment and practical good sense? St. John Long, who put healthy young women to death by his plan of *preventing* consumption, was patronized and defended by peers and peeresses, by a colonial governor, and senators of renown.

The other reason alleged in objection to the proposed alteration at the Dispensary is, that the medical officers now attached to it have not called for any thing of the kind, and that they would consider the change an imputation on their professional character. The latter idea scarcely requires serious refutation. Were they Hunters, Potts, and Abernethys, the same necessity for alteration would exist. However high the genius or talent of a man may be, it requires a certain portion of time for its exercise. The present officers of the Dispensary are men of ability and irreproachable character, exerting themselves, no doubt, to the utmost of their power in promoting the objects of the charity; and nothing would give me more pain than that any thing which this letter contains should be construed into a reflection on any of these gentlemen personally. Much may be due to them for their services; but in attending to their interests (which, it may be thought, are promoted by permitting them to have the exclusive medical charge) the interests of those for whom the charity was founded must not be neglected.

As respects the interests of medical men, it would accord, no doubt, with those of a smaller number, to have possession of such a charge in an hospital or dispensary; *but does it not oppose the interests of others, of equal merit and having equal claims, to be excluded from it?* Why should those possessing no advantage as regards strength of mind or intellect, but only as regards strength of legs and countenance (see remarks above), be allowed the exclusive occupation of such avenues to reputation and fortune, to the prejudice of others whose superiority and modesty prevent their resorting to the practices necessary to ensure success at the election? The present system of appointing so small a number of medical officers to these institutions (and for life) is a gross injustice to the profession as well as to the poor.

A dispensary is, in truth, a blessing or a curse to the community, according as it is well or ill administered. If well conducted

and credible reporters. For assuredly, much advantage to medical science would accrue from the accurate observation of the unaided and undisturbed efforts of nature in the cure of disease under homoeopathic treatment; and from the observation of the effects of such powerful agents for good or evil, as sudden changes of temperature, and the continued exhibition of large quantities of water, in all diseases and under all circumstances, according to the true and genuine hydropathic system.

by a body of sensible and well-informed men, devoted only to the welfare of the poor, it is a noble institution, reared in that truly christian spirit which labours to make amends for the inequalities of fortune, and to lessen those evils which the inevitable poverty of many must bring upon them. From it the sick poor may be supplied with the best and *speediest* assistance; while its numerous talented and zealous medical officers not only become better practitioners themselves by the experience thence derived, but have the opportunity of contributing towards the advance of the healing art. Where does such a dispensary exist? If, on the other hand, a dispensary is administered badly, if other interests than those of the sick have paramount influence in its management, it becomes a lure to the poor for their destruction, and has all the evil effects on its medical officers which have been noticed above.

These observations have more than a local bearing; they apply wherever there are dispensaries, and contending interests of medical men; that is to say, to every town and city in the empire. The letter had its effect; for though the proposal to increase the medical staff was negatived at the two meetings that took place before its appearance, the motion was entertained, and carried, as we are informed, at the one held immediately afterwards.

CASE OF RECOVERY AFTER THE ARM AT THE SHOULDER-JOINT WAS TORN OFF BY MACHINERY.

A BOY, seven years of age, while playing about a sugar mill, was caught by the machinery, and before he could be extricated his left arm was torn off, bringing with it about two-thirds of the scapula. The deltoid muscle was torn off entire, and the clavicle was wrenched from its attachment to the trapezius muscle, and projected through the wound. Notwithstanding the large amount of surface exposed not the slightest hæmorrhage occurred. It was judged prudent to remove the remains of the scapula, the inferior and posterior portion alone remaining, and also to saw off the external third of the clavicle which protruded through the wound. No vessels required to be tied; the wound was closed by sutures and adhesive straps, and a compress with a bandage round the body completed the dressing. Every thing went on favourably. The feverish reaction was inconsiderable after the first day. By the fifth day it was found that the half of the wound had united by the first intention, and that the remainder was suppurating favourably. The sutures were

therefore removed, and from this time he rapidly recovered.—*New York Journal of Medicine.*

QUARANTINE.

M. AUBERT ROCHE has addressed a letter to the Academy of Medicine on this subject, in which he states, 1st, that Austria and England have abolished their quarantines; France has retained hers, therefore the sanitary regulations of Europe require reform. 2dly, Every ship that has arrived in Europe without plague has remained unattacked.

The reform proposed is founded on the assertion, easily refuted if false, that all cases of plague have occurred within eight days after the departure of the ship: the observations on which these assertions are founded extend over a period of 124 years. Scientific authors have been of opinion that the period of incubation may exceed eight days. These cases occurred, however, on shore, not on board ship at sea. The plague, it is said, may be carried; but this will signify little if, in all cases where it has been carried—and 64 such have occurred in 124 years—it has broken out at sea on board ship. M. Aubert insists strongly on facts and figures, and contends that no one fact can be adduced to refute his two main assertions; viz. that plague shews itself at sea within eight days after departure, and that a ship which arrives unattacked with plague remains so.

M. Chassinat, in a letter on the other side, cites the case of the Leonidas in 1835. This packet left Constantinople the 27th July, and Smyrna the 30th, both places being infected at the time with plague. On August 10th, a case occurred supposed to be gastro-enteritis; a second, and subsequently a third case ensued; the last proved fatal, and undoubted plague followed. M. Londe offered to prove, by official documents which he had seen, and would lay before the Academy at their next meeting, that the first case on board the Leonidas appeared within the first eight days.

This offer was accepted, and the letters of MM. Aubert, Roche, and Chassinat, were referred to the publishing Committee.

TUBERCULAR PERITONITIS.

THE symptoms of tubercular peritonitis are generally slight, not numerous, and frequently are unnoticed. They are, however, quite sufficient to warrant a positive diagnosis. The invasion of this disease has no fixed relation with the main affection, and may occur at any period of its progress. The first symptom of chronic peritonitis is enlargement of the abdomen, denoted by the uneasiness in his clothes which the patient experiences, if up and about. With this

there is dull abdominal pain, sometimes general, (either singly or co-existent,) increased by pressure and percussion, and unaccompanied by diarrhoea. Later, and at a very variable period, physical exploration, however, reveals *fluctuation*: and *meteorism*, to a greater or less degree, will be ascertained. After increasing to a certain extent, fluctuation will *diminish*, whilst the gaseous distension *persista*. Where abdominal meteorism is present from the commencement of the disease, without appreciable effusion, it will diminish after some time, leaving the abdomen firmly resistant under pressure, knotted, and the intestinal convolutions marked on the surface; and this tense elasticity persists with complete relaxation of the muscular parietes. Nausea and vomiting rarely occur, unless acute peritonitis should supervene. There is great diversity in the intensity of the rational symptoms; sometimes the feeling of uneasiness, or even positive suffering, is so great as to occupy constantly the attention of the patient; at other times there is entire absence of pain, and the physical signs alone announce the existence of the affection. Ordinarily, the symptoms just enumerated persist, or increase, till death occurs; but sometimes, when the disease is intensely chronic, the abdominal symptoms disappear, and the thoracic symptoms only attract notice. This happened in the first case. Sometimes abdominal effusion is absorbed with great rapidity, and, on examination after death, you find only general intestinal adhesion by recent false membrane, when, but a few days before, there was positive evidence of fluctuation.

The symptoms of chronic peritonitis, though few, are of great value, from their constancy and regularity, in reference to diagnosis. Dr. Louis places the greatest confidence in them, and states (*Recherches sur la Phthisie*, 1843, p. 272) that through them he has been led to the successful diagnosis of phthisis in persons in whom there was little or no cough, and where the most careful physical exploration gave no evidence of thoracic disease.

To resume, we may say, that where we have general abdominal pain, of moderate intensity, but still sufficiently annoying, without diarrhoea, accompanied with increase in the size and sonorosity of the abdomen, with the supervention of manifest fluctuation, and independent of any organic affection of the viscera, the liver especially, kidneys, or heart, with subsequent absorption of the effused fluid, leaving a slight, but general, gaseous distension, with the intestinal convolutions well defined, and with this, great loss of strength, which cannot be referred to the condition of the lungs or of the excretions,—when, we say, we have this

combination of symptoms, we may, with great safety, diagnose tubercular peritonitis.—*Philadelphia Medical Examiner*.

NEW PRACTICE IN THE REDUCTION OF A DISLOCATED THIGH.

W. JANIG, aged 32, a strongly-built, muscular man, in struggling with another man, who was attempting to escape from prison, rolled down from the top to the bottom of a flight of stone stairs, twenty-four in number. On reaching the ground he felt severe pain in the left hip, but sprang to his feet and attempted to follow the malefactor; the left leg, however, failed him at once, and he fell prostrate again. A dislocation of the head of the thigh-bone downwards and backwards was immediately detected, and attempts, continued for several hours on two occasions, after the use of the warm bath, venesection and tartrate of antimony, were made to replace the bone; but in vain. Further assistance was sought, and next day, the patient having been again bled to fainting, and kept for a long time in a hot bath at 100° F., a third very determined effort to reduce the dislocation was made; but with no better success than on the two former occasions: the head of the bone could be brought to the edge of the acetabulum, but there it stuck as if wedged, and the moment the extension was relaxed it slipped back into the sciatic notch. It was now resolved in consultation to make the patient *dead drunk*, with a view to effecting the reduction; and the landlord of the house where the patient lay, having been taken into confederacy with the doctors, the new ally kindly gave the patient a *bottle of port wine, and half a bottle of rum* in divided doses, in order to *refresh* him, so that when the confederates returned, they found the man "in a *soporose condition*, and evidently in the *desired state of universal muscular collapse*." The patient was lifted out on his mattress, and the reduction was now accomplished without his appearing to know anything about the matter. The patient was very long of recovering the use of his limb in any considerable degree, and seems narrowly to have escaped with his life from an attack of gastric nervous fever during his convalescence from the injury. He is probably lamed for life.—*Casper's Wochenschrift*, No. 9, 1844.

THE ROYAL ACADEMY OF SCIENCES, PARIS,

HAVE awarded a prize of six thousand francs in equal moieties to M. Stromeyer of Hanover, and M. Dieffenbach of Berlin,—To Stromeyer, for having first conceived the operation for squint, and shown its practicability on the dead body; to Dieffenbach, for having first

successfully performed the operation on the living subject.

The Academy have further recompensed Messrs. Bourguery and Jacob with a sum of five thousand francs, for their Iconography of Surgical Anatomy and the Operations of Surgery.

The Academy have still further rewarded M. Thibert with a sum of four thousand francs, for his imitations of morbid structures, in a kind of papier maché, (carton-pierre), coloured, which, say the Commissioners, "reproduce every variety of morbid structure with the greatest fidelity in regard to form, relief, and colour, and with the strictest attention to the last minutiae of detail."

The Academy have still further decreed a sum of three thousand francs to M. Longet for his work On the Anatomy and Physiology of the Nervous System of Man and the Vertebrata, as containing "a great number of facts relative to the diseases of the nervous system, which scattered, and isolated hitherto, are here collected, collated, and discussed in a very complete manner. And to M. Valleix they have voted a sum of two thousand francs for his work on the Neuralgiae, as calculated to advance the healing art, and to improve the diagnosis and therapeutics of an important class of diseases.

They have finally desired that honourable mention be made of the inquiries of M. Amussat in regard to the wounds of arteries; of the work of Messrs. Serrurier and Rousseau upon the Diseases of the Air-Passages of Man and certain Animals; and of the treatise of Dr. Ph. Boyer on the treatment of Ulcers by means of compression effected with strips of adhesive plaster.—*Comptes Rendus*, No. 9, 1844.

PRESERVATION OF PATHOLOGICAL SPECIMENS.

M. PIGNÉ announces that a solution of creosote, in the proportion of 4, 5, 6, 8, or 10 drops, according to circumstances, to the litre or pint and three-quarters of water, forms an excellent and of course very cheap liquor for the preservation of pathological specimens. An entire subject, or any portion of it, kept in the solution of 10 drops, preserves all its physical characters and properties unchanged for an indefinite length of time. Pathological specimens that have been shrunk and blanched by twenty years keeping in spirit, are very speedily restored to their original form, size, colour, and pliability, by being transferred to the creosote liquor. Portions of blood, pus, urine, &c. may be kept in it without undergoing any change, and examined at leisure.—*Gazette Médicale de Paris*, Mars 9, 1844.

ILEUS FROM A

TURNING OR TWISTING OF THE BOWEL ON ITS AXIS.

A MAN, in loading his waggon with clover, had occasion to mount and jump down again repeatedly, after which he was taken with colic pains and obstinate constipation. All remedies and means were vain, and the patient died on the fifteenth day of his illness. The ileum at its lower extremity, where it terminates in the cœcum, was found simply turned or *twisted upon its axis*. The turn was single, but the piece of intestine was as securely confined as if it had had a noose of thread cast over it. The small intestines were slightly reddened, and excessively distended with gas; the great intestine, on the contrary, was pale and contracted. The twisted portion of gut being set free, it was found quite pervious and uninjured. Would the use of quicksilver have been of any service in this case?—*Dr. Koschny, in Casper's Wochenschrift*, No. 4, 1844.

GELATINE AS AN ARTICLE OF FOOD.

THE nutritive or non-nutritive qualities of pure gelatine have so frequently been made the subject of question and inquiry, that it is one which is now somewhat flat and stale. Nevertheless, the point is interesting in itself, and has not yet been held as definitively settled. The Institute of Amsterdam have gone into it very lately, and have come to the following general conclusion upon what appears to be very sufficient grounds, viz.:—That gelatine has no nutritious qualities when taken by itself, and it acquires none when combined with other articles of diet.—*Comptes Rendus*, 11 Mars; and *Gaz. Méd. de Paris*, 16 Mars.

HEATING POWER OF THE SUN.

Few of those who have not turned their minds to the particular study of HEAT, have estimated at its full amount the calorific power of the sun. We seldom, in these latitudes, find bodies exposed to the direct rays of the sun to attain a higher temperature than is indicated by about 120° Fah. But the celebrated M. de Saussure, by means of a little box constructed of wood, and lined with charred cork, obtained a temperature of 221° Fah., the temperature of the external air being at the time 75°; and Professor Robison, in the cold climate of Edinburgh, by means of a somewhat similar apparatus, frequently obtained an indication of 230°, and once, circumstances being favourable, of 237° Fah. The sun's rays, therefore, not concentrated in any

way, but simply accumulated, have a temperature much above that of boiling water, in the 52nd parallel of northern latitude.

FIBROUS TUMOR OF THE BREAST.

The Royal Academy of Medicine of Paris have lately spent several days in discussing the above-named subject, which had been introduced by M. Cruveilhier. There occurred, however, very little light to be obtained upon the matter. The learned mover of the question failed to shed any, and each successive speaker appeared to be more in the dark about it than the other. A correspondent of the *Gazette des Hôpitaux* (No. 33), explains the dilemma in which the honourable Academy found itself placed in a very satisfactory manner. He says, "M. Cruveilhier, a conscientious and enlightened physician, and moreover a Professor of Pathological Anatomy, comes down to the Academy one fine day, and delivers himself in these terms: 'Gentlemen, there are fibrous tumors of the breast, and they are common.' Now it was obvious to us all along that no member of the Academy had ever seen one of these tumors, so that it would have been very natural for some one to have said, 'Will the Professor be good enough to show us one of these bodies, for I myself have never either touched or seen such a thing?' But no; one was fearful of hurting M. Cruveilhier by seeming to call in question his information and good faith; another was afraid of exposing his own want of information, and so damaging his reputation: what a dilemma, had some journal published such words as these,—'M. X. never saw a fibrous tumor of the breast, a disease, nevertheless, which is very common;' and a third, by so simple a question, would have cut short all discussion, and seen himself forced to keep his eloquence bottled up, which would have been very distressing to him. These and various other reasons account for the circumstance that no one said to M. Cruveilhier, *there is no such thing as a fibrous tumor of the breast*. No one went further than to say, *there are few fibrous tumors of the breast*. Hence the harangues which we have been compelled to abide, and those with which we are still threatened.'

A CASE OF IMPERFORATE HYMEN.

By WM. SHULTICE, M.D., of Mathews, Va.

On the 12th of October, 1843, I was called upon to visit Miss G., of this county, a young lady, *ætat* 18 years, who had enjoyed uninterrupted health until within the two years last past. Upon examination I found her afflicted with the bilious remittent fever of the season, for which I treated her in the usual manner.

Her mother informed me she had a "lump in her side" which she did not like, and which caused her much uneasiness, and desired me to examine it. I discovered upon examination a considerable tumor in the abdomen, reaching as high as the umbilicus. The patient presented the appearance of a female about seven months advanced in pregnancy.

I stated to her and her mother the necessity of an examination *per vaginam* before I could form an opinion as to the true nature of her disease. Her mother had informed me she had never menstruated. Upon making the examination, to my surprise, I discovered, that the *os externum* was completely closed by a dense, unyielding membrane, which presented an impenetrable barrier to the finger, and of course obstructed the passage of the catamenia, and caused the tumor in the abdomen.

I immediately informed her and her mother of the necessity of an operation for her relief. At first the idea of such an operation was revolting to her feelings; but the necessity for its performance was so plain, that she consented.

After a few days, when the fever with which she was affected had subsided, I performed the operation by placing her on the edge of the bed, in the position for lithotomy. Upon opening the labia externa a tumor presented itself, protruding externally as if pressed outwards by a fluid internally. To the touch it appeared to yield. The hymen closed the vagina completely from the perineum to the orifice of the urethra, and of course presented an obstruction to the passage of the catamenia.

With a large abscess lancet I made a free incision through the hymenial membrane, and there immediately ensued a gush of a dark, grumous fluid, of the colour and consistence of tar. It was not coagulated, neither did it emit any odour, but presented exactly the appearance described by Denman, in a similar case. As related by him, the only change the menstrual fluid appeared to have undergone, was a lessening of the more fluid parts by absorption.

The fluid continued to discharge until six pounds had passed, when the pulse becoming feeble and the patient exhausted, I enlarged the orifice by means of a probe-pointed bistoury, and placed a tent between the parts to prevent adhesion. She was then placed comfortably in bed, and some stimulants administered.

There continued to flow through the vagina, for several days, the same dark, grumous fluid, until, from the information I received, at least two more pounds must have escaped, making in all eight pounds of menstrual fluid.

The health of this young lady had been for

about two years affected. She had been during that period, attacked monthly with pains in the back and lower part of the abdomen, which were ascribed to a want of the natural secretions. But neither she, nor her friends, had the most vague idea of the true nature of her situation. The tumor in the abdomen has entirely disappeared, and her health is rapidly improving. — *American Journal of Med. Sciences*, Jan. 1844.

THE AMERICAN EDITOR'S TRAVELLING EXPERIENCE

AMONG HIS COUNTRYMEN.

IN leaving the country watered by the Alabama, Coosa, and other beautiful rivers, we may be permitted to say, that in forty days' active travel we have everywhere met with the greatest hospitality. We have encountered neither robbery nor insult, nor more than a dozen drunken men, nor seen a single bowie knife, nor a fist-fight, nor heard six doctors backbite their brethren, nor spoken to one tripping physician, *sicce rara avis!* — *The Western Journal*, No. 43.

PREPARATIONS OF IRON.

To the Editor of the Medical Gazette.

SIR,

ON my return to town, after a short absence, I perceive that you have admitted into your pages, a very elaborate, but very weak attack upon me by Mr. Hemmingway: I trust to your sense of justice to admit my reply. At the commencement of my career as a pharmaceutical chemist in London, I introduced to the notice of the profession certain preparations of iron which had been employed for eight or ten years in France, without being noticed in this country; for the investigation which led to the use of several new salts of that important medicinal agent, we are indebted to M. Beral, a well-known and highly respectable pharmacien of Paris. I underwent considerable labour and expense in preparing the several salts of iron described by Beral, in order to suit them to this country in price, to ascertain through the medium of medical friends their remedial value, to make them known through the usual channels of medical information, and by advertisement. In the course of my investigations, I found that citric acid and iron entered into combination with various bases, forming a number of new compounds. A list of these was published. But as many of these had not been tried as remedies, little more was said about them, than that I kept them for any medical gentleman to employ who might wish to try their effects. There is responsibility incurred by persons who introduce new remedies to the profession, which chemists

would do well to consider, since much injury may accrue from untried preparations. As soon as the profession perceived the great improvement which these salts were upon former preparations of iron, a considerable demand for several of them was created, and in the spring of 1842 I was making the "Citrate of Iron" in large quantity. At this juncture, as it appears from Mr. Hemmingway's letter, the "respectable" firm of Savory and Co. employed him to attempt the imitation of these preparations, and if his success has been no better than is indicated by his letter, his time has been sadly misspent.

To any chemist I need not say Mr. H.'s letter proves nothing but his own inability to pursue such an investigation, and I scarcely think any one can be misled so far as to mistake his verbose story for sense or information. For example, Mr. H. thinks he has discovered a salt, all he knows of which is, that it is of "an amber colour:" he leads us to infer that to analyse a salt is unnecessary, since when two or three substances are put together, we must know its chemical composition. He thinks that a sweet taste in a compound is a proof of the existence of sugar;—and thus he proceeds, assuming himself to be qualified to dictate a nomenclature for what he so well understands.

Mr. H. gives a summary of the citrates of iron, in which he does not even mention one of the most energetic, and that one the basis of the citrate of quinine and iron: this proves how deeply he has studied the subject of which he writes, and what the nature of his claim is, to the discovery of the "amber-coloured salt," upon which your present correspondent has failed to throw the slightest light. There is in the preparations of iron much to interest both the chemist and medical practitioner; the former, since the chemical relations of iron and its combinations have by no means been fully studied, and the latter, because abundant experience has proved that the effects of iron on the animal economy and in the treatment of diseases vary with the state of the iron in relation to oxygen, and the acid or metalloid with which it is combined, to an extent which at present is very inadequately understood. Abundant experience has, however, proved that the citrate of iron of Beral is a valuable remedy; which every body knows, contains a portion of ammonia. I have already published my reasons for not altering Beral's designation of this salt.

Then there is another citrate, the citrate of peroxide and protoxide of iron, which has a very energetic action as a remedy. Many gentlemen have assured me that in *tic-douloureux*, they have found nothing equally efficacious. The combination of this with

citrate of quinine is now in most extensive use, and most satisfactory information has reached me respecting its therapeutic value.

The uses of iron in the treatment of diseases would be an excellent subject of investigation for a practical physician. The chemical part I trust ere long to accomplish myself.—Your obedient servant,

LLOYD BULLOCK.

April 5, 1844.

DR. ANDREW MOIR.

It is with much regret that we announce the death, on the 6th ult., of Dr. Andrew Moir, Lecturer on Anatomy in King's College Medical School, Aberdeen. Cut off at the early age of 38 years, by contagious fever, caught in the discharge of his professional duties, his death has deprived Aberdeen of a townsman of whom she had reason to be proud, and her medical school of one of its most efficient teachers. What adds to the melancholy nature of the event is, that Dr. Moir has left an aged mother, a widow, and three very young children (the last born two days after his decease), totally unprovided for, without relatives, and destitute even of temporary supplies. A subscription has been entered into among the late Dr. Moir's friends and the humane, to provide a fund for the immediate maintenance of his destitute family. Drs. A. Harvey and G. Dickie, Aberdeen, have kindly undertaken to receive contributions in their behalf.

DR. BARLOW.

Our profession has just sustained another severe loss in Dr. E. Barlow, of Bath, who died last week. Dr. B. had not been seriously indisposed for any length of time; he appeared to fail all at once; both mind and body seeming to be stricken. He made little complaint, save of weakness; he passed a considerable quantity of pale urine, which, on examination, was found to be of low specific gravity, alkaline, and highly albuminous. Disease of the kidney was diagnosed, and, from the symptoms, disease that was likely to prove fatal in no long time. A fortnight more, and his race was run. One of the kidneys was found highly congested, of a deep red colour, and with white granular deposits through the whole of its substance; the other was pale, but granular also. The other viscera were sound. Dr. Barlow is best known to the profession by his contributions to the *Cyclopædia of Practical Medicine*, which are able, and prove him to have been a careful and accurate observer. No man ever enjoyed in a greater degree the love and esteem of his friends and associates.

APOTHECARIES' HALL.

Gentlemen who have received Certificates,
April 4.—D. C. Noel, Jersey.—J. Horton,

London.—J. L. Williams, Carmarthen.—N. S. Glazebrook, Liverpool.—B. L. Jemmet, Grenada, West Indies.—T. Gaskell, Knutsford, Cheshire.

NOTICE TO CORRESPONDENTS.

The letter of "M.D. and an Anatomist" is too severe and personal. The subject of Inflammation is surely, of all others, that on which every man may have his say without offence to any one. We should like to hear from M.D. upon another topic, and when his back was not up.

We are sorry we cannot give "A Reader," who writes from Glasgow, the information he desires. We have not been able among our friends here to ascertain whether Dr. Badham had or had not abandoned his purpose of publishing his lectures. We should be delighted to learn that he had not. Neither have we seen any portrait of that distinguished physician.

We trust that the vaticination of "Sherborniensis" will not prove true; and we hope not only to have him on our list of readers, but also among the number of our contributors.

Dr. M. R.'s paragraph is an advertisement, and, strictly considered, would subject us to pay duty to the Queen did we insert it.

MORTALITY IN THE METROPOLIS.

Deaths from all causes registered in the week ending Saturday, March 30.

ON THE
FUNCTION OF THE LYMPHATIC
VESSELS.*

BY ROBERT WILLIS, M.D.

(For the London Medical Gazette.)

ALL the advances lately made in physiology, instead of rendering more obvious the end for which the vessels entitled *lymphatics* or *absorbents* exist, seem but to have made their presence a greater anomaly, their function a greater enigma. After having been left for half a century or more in exclusive possession of the office of *absorbing*, it is generally known that M. Magendie has in these times held himself authorized to conclude, from his experiments, that the lymphatics had nothing to do with absorption, this act, according to him, being performed solely by the veins. But while he thus deprived the lymphatics of their ancient duty, this distinguished physiologist has not ventured to assign to them any new office, and has consequently left them to be considered as a superfluity—a something that might have been dispensed with in the nicely ordered mechanism of the animal machine, where, however, there is very certainly nothing superfluous—no organ without its function, no function without its appropriate instrument.

Professor Rudolph Wagner, writing so lately as the year 1841, can see no reason for the existence of the lymphatic system. "Neither anatomical nor physiological considerations," he remarks†, "render any satisfactory account of the import and office of the lymphatics." The field, therefore, seems as open to inquiry, in regard to the end for which this system of vessels exists,

as it is in regard to the office of the spleen, the thymus, the thyroid, &c.

In a paper which I had the honour of laying before the Royal Society very lately, "On the Special Function of the Skin," I shewed the influence which the dissipation of a certain amount of simple water by the sudoriferous glands exerted upon the current of blood returning from all the peripheral parts of the body to the heart, and insisted upon this as the means by which venous endosmosis or absorption was chiefly secured.

In perusing what has lately been written of highest authority on the subject of absorption, it will be seen that the necessity for a difference between the fluid that is ministering to the nutrition, or feeding the secreting faculty of an organ, and the fluid that is returning from this organ, having done its office, has very constantly been felt; but it seems to me that the means by which this needful difference is effected, to say nothing of its nature, has not hitherto been explained. The faculty of imbibition, to which there is at this time a tendency among physiologists to refer all absorption, is always understood as engendered between fluids or matters in a state other than that of homogeneity or equiponderance. Were the several elements, both fluid and solid, of the tissues which compose the animal body, all in the same state, chemically and physically, there would be no interchange of matters between them—the walls of the arteries would not exude, those of the veins would not imbibe. "If the same portion of blood were constantly exposed to the same part of the tissues," says Müller‡, "imbibition, after a time, would necessarily cease. The motion of the blood must be so far favourable to imbibition, therefore, as it removes what has already been absorbed, and thus renders constant the cause of endosmosis." The necessity for a difference

* Read before the Royal Society, March 16, 1843.

† Physiology, English version, page 444.

855.—XXXIV.

‡ Physiology, English version, page 267.

implying endosmose between the outgoing and incoming current of blood, is distinctly expressed in this passage; but neither here, nor in any other part of Professor Müller's work, is the reason given for any difference that may perchance exist between the one and the other. To say that the arteries exude and the veins imbibe in the course of the circulation, is to state an admitted fact, but not to make known the means by which the former are disposed to exude and the latter to imbibe. Did not the blood, between its outward and inward course, lose something by which its density was augmented, there would be no endosmose into the returning channels, in the sense in which the word is generally understood in physiology, viz. penetration, with increase in the bulk of the body or liquid penetrated. I have, as I conceive, shewn that the sudoriparous glands form one element in a great system existing for the especial purpose of abstracting water from the blood, and thus preparing the conditions essential to the return into the venous circulation of the fluids transuded by the arteries for the purposes of nutrition and vital endowment. I say *one* element in a system having this important office entrusted to it; for the influence of the sudoriparous glands could not be expected to extend to any great depth below the surface; the subcutaneous veins transmitting a fluid more dense than that of the arteries which feed them by the whole amount of the perspiration which has been thrown off, will effectually drain the tissues through which they pass; but they would exert little or no influence upon deeper parts; these would still be liable either to be overwhelmed by the flood of plasma poured out upon them by the nutrient arteries; or otherwise, there being no attraction exerted between these parts and the contents of the capillary arteries, all exudation would cease. It appears to me that nature has come to the aid of these deeper tissues by means of the vessels entitled *lymphatics* or *absorbents*, the essential function of which I believe to be the abstraction of a certain quantity of the watery element of the blood, for the specific end of rendering the returning stream of greater density than the outgoing stream.

The very first question that now presents itself is this: what is the nature of the fluid which the lymphatic vessels transport? Is it watery and of less density, or is it thick and of greater density, than the blood or liquor sanguinis? If it were more dense than the liquor sanguinis, it would have no influence in augmenting the density of the blood returning to the heart in the veins; if less dense, on the contrary, in proportion to the excess of its water over that of the blood will be its influence in condensing this fluid in the veins, and in fitting them for draining

the tissues through which they pass. Now the specimens of human lymph, as well as those of the lymph of healthy quadrupeds, which have been analysed, have all been found of density greatly inferior to blood. In the lymph examined by Marchand and Colberg, which was obtained from an open lymphatic vessel upon the top of the foot, the quantity of water amounted to 96·92 in 100 parts. In that analysed by Bergman, which was obtained from another subject under similar circumstances, the quantity of water was 96·10 in 100 parts. And in that examined by Dr. G. O. Rees, which was obtained from the abdominal lymphatics of a healthy donkey, the quantity of water was 96·53 in the 100 parts. These results, obtained by different chemists of acknowledged accuracy, at different times, agree very remarkably, and may be taken without limitation as correct; but the quantity of water which enters into the composition of the blood of man appears, from the multiplied analyses of M. Lecanu, to amount to no more than from 77·8 to 82·7 in the 100 parts. The lymph is therefore a much more attenuated fluid than the blood, and being so, the blood will be inspissated, and made apt to imbibe in the same ratio in which the watery lymph is abstracted from its mass.

The difficulty that presents itself to the mind at this stage of the inquiry, is to conceive the means by which the lymph is separated from the blood. It cannot be by a merely mechanical or physical process akin to or identical with imbibition. Magendie and his scholars refused all absorbing power to the lymphatics; and if the expression be used to signify physical imbibition to a striking extent as it is carried on by the veins, I believe that they did so with perfect propriety. The veins are, in fact, the only *absorbents* in the strict sense of that word; i. e. they are the only structures whose office in addition to that which they have as channels of the returning current of blood, is connected with or dependent on their capacity to imbibe. Even the lacteals, as I shall have occasion to show, form no exception to this rule. All the tissues of the body imbibe, it is true, but this they do very slowly in every instance, save in that of the veins, and except in reference to these vessels, and perhaps the intestinal villi, function seems in no case to be connected with the mere physical capacity to be quickly penetrated by fluids. Function is, in fact, very often directly opposed to endosmose; as witness the separation from the relatively dense blood, of the watery saliva, pancreatic juice, sweat, and urine. The admitted laws of endosmose declare that such fluids as these ought not to quit the blood. There can be no question, however, of every tissue and organ in the body being endowed

with an especial elective and divellent power, connected doubtless with its development and growth, by which it selects from the plasma, with which it is bathed, the peculiar principles required for its origin and nutrition: bone takes gelatine and phosphates of lime, muscle takes fibrine, the brain and nerves take albuminous and fatty matters, &c. And then the glandular organs have very peculiar, if not perchance additional *creative* powers, by which, whilst they are nourished, they separate from the blood or prepare and pour into appropriate channels various fluids which are spoken of as their *secretions*.

In the same way precisely would it seem that the lymphatic and lacteal vessels perform their functions. These vessels may, in fact, be viewed as the essential elements of an universally distributed gland. Their walls and sacculate commencements have been shown by the latest and best observers* to be composed of an aggregation of granular matter, of nuclei, and of cells in various stages of development, precisely similar, as I conceive, to the ultimate elements of every secreting organ known. Here, as elsewhere, nuclei in a ceaseless state of reproduction, attract a certain quantity of granular matter about them, and then they become surrounded with a delicate envelope filled with fluid—they have grown into cells; and these having attained maturity, and being then in contact with the internal surface of the lymphatic vessel in whose wall they have grown, they give way and shed their contents into its cavity. The secreted fluid in reference to the lymphatic system is the lymph, a fluid having on an average, as has been seen, about 96½ per cent. of water, and 3½ per cent. of solid matter in its constitution, this solid matter being identical in chemical composition with that of the liquor sanguinis†. The lymphatics, then, or, to speak more accurately, the cells of which their walls are composed, in the course of their evolution exert a special affinity for the watery element of the blood; and abstracting this from the fluid that is circulating in the capillary arteries, they in the same proportion inspissate the current which is returning to the heart in the veins, and thereby endow it with powers of imbibition or endosmosis to effect a ceaseless

and rapid change in the plasma which is transuding the walls of the arterial system at every point.

The assumption of the chyle by the lacteals, or lymphatic vessels of the intestines, is effected in the same way as that of the lymph in other parts of the body, but unquestionably with a greater amount of *penetration* here than elsewhere. Modern physiology repudiates the idea of imbibition by open mouths; the lymphatics of the intestines begin, as they do everywhere else, in the form of coecal sacs or canals, and the only differences observable between their structure and that of the lymphatics generally, appears to consist in the higher development of the essential elements of the system—the nucleated cells—which is here conspicuous. The absorption of the chyle is readily to be explained in this way: the substance of the intestinal villi where they are met with, that of the spongy tissue which still forms the inner layer of the small intestines, where they fail, like the substance of other tissues, is in a state of perpetual growth and decay. The decay here, as in glandular organs generally, takes place in the interior, towards intercellular channels or ducts; in the case under consideration, towards lymphatic or lacteal vessels. But the cells of which the intestinal villi and pulpy inner membrane of the bowels principally consist, being evolved in mediate contact with the chyme, are penetrated by some portion of this; they gradually attain maturity, and then they give way and discharge their fluid contents mingled with a peculiar granular matter into the ducts with which they are in relation. The fluid contents are the *chyle*, the ducts are the *lacteals*.* The contents of the nucleated cells of the intestines, it is to be observed, are only white and milky when there is chyme, and that even of a certain description, in the intestines; when there is none of this chyme present, their contents are transparent and colourless, or nearly so, as is

* Doellinger appears to have been the first who approached the truth in this matter. He held that the villi of the intestines incessantly reproduced on their exterior or intestinal aspect by the aggregation of particles of chyme, in the same way as the germinal membrane of the embryo grows by the apposition of particles of the yolk, underwent in the same measure solution on their interior, and by this process formed the chyle of the lacteals. This is obviously the germ of an idea that has proved most fortunately prolific since Doellinger wrote (vide *Froriep's Notizen*, Bd. I., No. 2, 1828). Had he but viewed the aggregations of nucleated cells which compose the intestinal villi as derived from the common nutrient fluid, he would have anticipated Purkinje in his beautiful views of the intimate nature of glandular secretion (vide *Versammlung der Naturforscher und Ärzte*, Prag, 1837, in *Isis von Oken*, No. 7, 1838, p. 578), views that have very recently been most satisfactorily extended and variously demonstrated by Mr. Goodair (vide *Transactions of the Royal Society of Edinburgh*, vol. xv. p. 295, 1842.)

* Vide particularly the *Allgemeine Anatomie* of Henle, S. 530, and Tab. v. fig. 26.

† There is every reason to believe that blood-discs are developed in considerable numbers in the lymphatic vessels: the albuminous fluid which they contain is fitted, we must presume, to prove the matrix or blastema of these important cells, and they are evolved in it probably as a matter of course, their formation and evolution being assisted by the elaboration which it undergoes in the lymphatic glands. I cannot, however, regard this part of the office of the lymphatic system at large as otherwise than secondary, and in some sort adventitious, to that which is advocated for it in this paper.

also the product of their maturity and rupture, then entitled lymph, no longer chyle. Chyle indeed, only differs from lymph, in containing a relatively larger proportion of albuminous and fatty matter, which is exactly what might have been expected in the fluid that is bringing fresh pabulum for the use and maintenance of the economy, albumen being the representative of the azotized fat of the non-azotized elements of the animal body.* I only pause here to observe, that notwithstanding the mass of fresh material with which the lacteals are charged, they still transport a fluid of much less density than the liquor sanguinis, and are, therefore, in a condition to execute the important office which I have assigned to the lymphatic system generally.

The anatomical distribution of the lymphatic vessels is in complete harmony with the views now taken of their vital function. In conformity with the principle of organs being found near to the places where their office is wanted, the office of the lymphatics must be general, inasmuch as the system is general. Mr. Lane has, however, called particular attention to the fact that the lymphatics are by no means ramified like arteries, veins, and nerves, to every constituent particle of the body. They are never seen save as vessels of a certain magnitude, that may be followed from the glands of the arm-pit and groin downwards, with the naked eye, by means of the knife and forceps to the very extremities of the fingers and toes. They run under the skin and in the intermuscular spaces, in lines more or less parallel to one another, and for long distances without receiving any lateral branches, although they frequently inosculate. Instead of growing continually, and from twigs and branches becoming trunks, in their upward course, like veins, the principal lymphatic channels on the dorsum of the foot, and on the back and palm of the hand, are actually seen dividing into great numbers of somewhat smaller canals, which then proceed upwards, and only come together again as they approach a cluster of lymphatic glands. The object is evidently to *diffuse*, not to concentrate the influence of these vessels. These lymphatics of the extremities, in a word, have everywhere the same character, and bear the strongest possible resemblance in their disposition to the tile or covered drains of modern agriculture; and they have, in fact, something of the same duty as these to perform. It is only on the serous membranes surrounding the viscera that the lymphatics have rather more of the appear-

ance of veins in their mode of distribution; still, even here, they are not in general anarising extensively and dividing into branches and twigs successively more and more minute until they escape the eye, except on the under surface of the liver; they rather proceed in a fasciculated manner, like bundles of rods. Speaking of the lymphatics of the viscera, Müller says expressly: "I am acquainted with no absorbent vessel that is not visible to the naked eye" (Physiology, p. 282), a conclusion that is borne out by the late researches of Mr. Lane (Cyclopædia of Anatomy, vol. iii. p. 217). It is now very generally agreed that the lymphatics are only disposed in the spaces between, and upon the surface of, organs; a few canals may also accompany the larger blood-vessels of the viscera for a certain way on their destination; they very certainly do not penetrate the substance or parenchyma of any organ. The mercurial injections of Fohmann, Panizza, and others, made by pushing a pipe at random into the filamentous tissue and parenchyma of organs, are acknowledged by the best anatomists to be injections of the interorganic areolæ, not of lymphatic vessels. The vicinity, not the immediate presence, of lymphatic vessels, therefore, suffices for the economy; and this accords with the views of the office which I have advocated for them.

The same views seem to acquire additional and peculiar support from the singular development of the lymphatic system which we observe in tortoises, lizards, and serpents—animals in which the common integument is obviously unfitted for the elimination of water, or watery vapour, and in which some substitute for this was therefore necessary. In these creatures, the lymphatic system may be said, without exaggeration, to be enormously developed; it is here of such extent and capacity that it is actually furnished with contractile sacs or hearts in various situations more or less remote from the origin of its constituent canals, for the propulsion of its contents towards the central organ of the circulation. Whether there be a corresponding increase in the number and magnitude of the lymphatic vessels in those higher animals which are covered with a horny or impervious integument, such as the manis and armadillo, I do not know, and have no opportunity of ascertaining, but I should anticipate that this was the case.

It is also important to observe that in certain diseases where the function of the skin is diminished, as in dropsies, the lymphatic system acquires its highest state of development. To display the lymphatics, anatomists always select the body of one who has died of some disease complicated with general dropsy.

* Vide the analysis of lymph and of chyle procured by Mr. Lane from the same animal at the same time, by G. O. Rees, M.D. F.R.S., in LONDON MEDICAL GAZETTE; and Mr. Lane's excellent article, Lymphatic System, in Cyclopædia of Anatomy and Physiology.

The relationship of the lymphatic system at large with the capillary circulation, and its subserviency in the direction already indicated, are still farther proclaimed by the manner in which it is finally connected with the blood-vessels. The watery fluid appropriated by the lymphatics is not poured into the veins in the vicinity of the parts and organs where it is gathered; this would have had the effect of again attenuating the returning current, and undoing all that had been done*. The contents of the lymphatics are added to the blood only at the moment of its entering the heart—at the nearest eligible point, it may be said, to that organ, from whence it will immediately be sent to undergo exposure in the lungs, and, besides the special purgation which it there receives, to lose so much water as will give the tide in the pulmonary veins a somewhat higher density than that in the pulmonary arteries, and so fit it to effect the drainage of the delicate tissue of the instrument of respiration. This, in fact, I hold to be the end of the pulmonary exhalation, an excretion which, although it may be in some measure physically unavoidable, is still made subservient to an important vital act.

As a final confirmation of my views in regard to the import and office of the lymphatic system, I would yet further refer to the singular amount of disturbance which ensues in the system generally upon any implication of the functions or structure of the serous membranes, which may be regarded in the main, I conceive, as contrivances for the accommodation of large numbers of lymphatic vessels†: for example, upon inflammations of these, adhesions to any extent of their opposite surfaces, &c. The mischief, in such cases, is commonly ascribed to interference with the motions of the organs whose serous coverings are interested, to the extent

* In some of the lower animals it would seem that all the lymphatics do not proceed to discharge their contents at the angle between the internal jugular and subclavian veins. This is held to be particularly the case in birds, in which several considerable lymphatic vessels have been described as joining the veins of the abdominal cavity. Lippi, who would have extended the same anatomical arrangement to man and the higher mammalia, totally failed to establish his views when in contact with the distinguished anatomists of Paris. The blood of the vena cava ascendens, however, having parted with the urine and the perspiration of the whole of the inferior extremities, might obviously be very considerably diluted without losing its capacity to imbibe from the tissues through which it passes.

† It is rather interesting to remark here, that the only two of the abdominal organs which are not included within duplicatures of the peritoneum, the pancreas and the kidney, are organs whose secretion is extremely watery. The blood in the capillary arteries of these two glands losing so much water as it does to their respective secretions, the blood in the capillary veins is rendered so dense that it suffices, with but little assistance from the lymphatics, to effect the drainage of their tissues.

of the surface affected, and so on; but it certainly depends on some cause of greater moment: I believe that the nutrition, that the life of the organ implicated, is compromised; the conditions necessary to the access of the nutrient fluid, and to the removal of effete matter, are interfered with, and hence arise the great amount of general constitutional disturbance first, and the constantly fatal effects in the end, which accompany affections of the serous membranes.

Thus far the function of the lymphatic system and skin has been considered as subservient to the needful interchange of the nutrient fluid, as this goes on through the spongy walls of arteries and veins. But it seems highly probable that the same function is efficient in an equal degree in facilitating the access and transit of the stream which supplies the nutrient fluid still included in the interior of arteries and veins.

Ever since the time of Cullen, physiologists may be said to have been in eager quest of a cause for the motion of the blood in the capillary vessels other than that which is derived from the mechanical force of the heart; and various bold hypotheses have been advanced on the subject.

The majority of the highest authorities in physiology at this time, however, recognise no moving power in connexion with the circulation of the blood among the more perfect animals, save that of the heart.

In acceding to this view, which I have no hesitation in saying that I do entirely, it is still open to us to inquire whether or not there be any means by which the course of the blood, along its more minute canals especially, is *facilitated*. It were vain to deny that the amount of resistance encountered by a somewhat sluggish fluid like the blood, propelled through canals of the 20 and 25,000th of an inch in diameter, must needs be very great; and yet the rapidity and obvious ease with which we see it shoot through such canals in the transparent parts of living animals, apparently drawn rather than driven through them, seems to indicate that everything like resistance is annulled.

It is certainly a very remarkable fact that the column of blood contained within a fine vessel of a living animal does not fill it from side to side as an evenly-mingled mass of coloured and colourless corpuscles and transparent plasma. The red discs are seen shooting rapidly through the centre as if repelled by the walls of the containing channel; the colourless corpuscles, on the contrary, suspended in a film of plasma of very appreciable thickness, interposed between the serried column of blood-discs in the centre and the walls of the vessel, move on, rolling over and over in contact with the bounding parietes, and as if attracted by them. This arrangement is unquestionably

one of high importance, of the nature of which I apprehend there can be little doubt, when the extent of apparatus is contemplated that is provided for the especial purpose of securing a different density between the outgoing and the incoming current of the circulating fluid, and a consequent ceaseless interchange of elements between these, in conformity with the laws of heterogeneous attraction, or endosmose.

The walls of the arteries, from the sigmoid valves of either great cardiac trunk to the limits of their peripheral ramifications, are incessantly transuding a fluid of considerably less density than the liquor sanguinis, which is either thrown off by the sudoriparous glands, and lost, or is appropriated by the vital act of the lymphatics, and returned at the proper moment for the uses of the economy; the walls of the veins, on the contrary, filled with a fluid augmented in density by the whole amount of water lost from the surface of the body, and transferred to the lymphatics, are incessantly abstracting, or rather are incessantly penetrated by fluids from the tissues through which they pass. In this way are different capacities of endosmose and exosmose continually engendered, first, as between the blood-vessels and the liquor sanguinis, and secondly, as between the liquor sanguinis and its containing channels, both efferent and afferent, from their beginnings to their ends.

RECORD OF CASES.

By THOMAS MAYO, M.D. F.R.S.

Physician to the Infirmary of St. Marylebone.

(For the Medical Gazette.)

[Continued from p. 17.]

THE method which I have adopted, ought, if I am doing it justice, at least to have the advantage of affording food to a love of novelty. For, whereas the language of system should be unvarying, so far as the system is rightly laid down, those details, on the other hand, by which the system is broken up into its ultimate varieties, present faces varying endlessly, according to the direction in which we make the fracture.

But if any doubt exist whether this latter process be one greatly desired by the present state of our knowledge, we need turn over but a few pages of any systematic writer of the present day in order to solve it. In the 76th page of Dr. Abercrombie on "Diseases of the Stomach and other Abdominal Viscera," we find the disorder gastro-

dynia admirably described under three heads.

1st, Pain occurring when the stomach is empty, and rather relieved by taking food.

2dly, Pain occurring immediately after taking food, and continuing either during the whole process of digestion, or till the stomach is relieved by vomiting.

3dly, Pain beginning from two to four hours after a meal, and continuing for some hours. Both the two last heads Dr. Abercrombie connects in some degree with inflammatory action. But when we proceed to those distinctions of treatment which may render this nosological division practical, we are met by an admission "that it is difficult to say what remedies are best adapted to each of these forms of gastrodynia; that he has found nothing of more general utility than the sulphate of iron, in doses of two grains, combined with one grain of aloes, and five grains of aromatic powder, taken three times a day; that oxyd of bismuth, combined with rhubarb in the same manner, is also very useful; likewise lime-water and small opiates; and that when the affection" (what affection?) "proves obstinate, it must be treated with topical bleeding and blistering, with farinaceous diet."

This is that triumph of pathology over therapeutics which our brethren on the other side of the water have so successfully achieved, and which, moreover, they have taught us to emulate. Meanwhile it is to be observed, that our wayward taskmaster, the public, is by no means satisfied with this vagueness of practice, however candidly avowed; and that they anxiously appeal from us to the various classes of irregular practitioners, whose pathological ignorance guarantees them against attaching undue weight to that element of the subject. Whether the system be infinitesimal or gigantic in the quantity of its doses or affusions, it is sure to be a therapeutical system, confidently laid down, and generally drawn out with much attention to minutiae and detail.*

* It is to be regretted that the able author of an article in the Quarterly Review, entitled "Brandy and Salt, Hydropathy and Homoeopathy," has not more largely entered into the important question, how systems of quackery gain influence with the public. Something they owe to the cause mentioned in the text; some-

The circumstances under which chalybeate remedies may be made available in the treatment of gastrodynia constitute an important topic. It is my present object to state some cases illustrative of a different principle of practice.

July 31st, 1831.—Mr. A——, a gentleman who had practised the medical profession in India, aged about 56, tall, thin, of the bilious temperament, having seen much service, and lived rather freely in early life, had been cured of a chronic affection similar, he said, to that which I shall presently describe, about four years ago, by a course of pil. hydrarg. continued for eleven weeks, and followed up by a visit to Carlsbad, and the use of its waters. About eight months ago, he was again attacked with pain at the epigastrium, constant in some degree, but greatly increased by eating, and attended by progressive marasmus. For this he had at first recourse again to pil. hydrarg.; but on this occasion it increased his uneasiness, irritating

his bowels. After trying ineffectually many remedies, among the rest, abstraction of blood, tonics, and alkalies he then had recourse to mercuria inunction, which he had continued to the day on which I first saw him viz. eight weeks, with manifest relief of pain, and improvement in his general feelings, but without any arrestation of the decline in strength and weight: the latter was ascertained weekly. His pulse was quiet, and of average strength and frequency; his respiration good; his evacuations healthy; his urine moderately acid, rather high coloured, not deficient in quantity.

Presuming that Mr. A—— required the internal use of a mercurial for its perfect effect, I exchanged the mercurial inunction for the pil. hydrarg. submur co. gr. v. to be taken twice daily. This course was continued to the 20th of August, with the most marked good effect; at first, he also increased in weight, but in this point he became stationary. This plan was exchanged in consultation with my friend Dr. Gordon, then of Finsbury Square, for the Decoct. Sarzæ Co. with Hydrarg. Oxyuriat. and Tinctura Cinchonæ. This greatly disagreed. On the 28th the Plummer's pill was resumed bis quotidie, with as much mercurial inunction daily as could be effected in an hour. No irritation of bowels resulted from Plummer's pill, as formerly from the Pil. Hydrarg.; and the plan was prosecuted continuously, though with varying quantities, to the 10th of November.

His diet meanwhile was simple, and very moderate; vegetables were not allowed; a small quantity of sherry was taken daily. It was observed by himself that the taking food was effected with least pain when his body was placed at an angle of forty-five degrees; and it was remarked that in that attitude a considerable hardness and fulness of the liver became observable two inches below the right ribs, which was totally unobservable in any other attitude.

Early in December, he went to Brighton, and thence he wrote me word that he had become confined in his bowels, which, he said, had in his former illness been one of the first facts observable on his improvement. He did not continue the Plummer's pill at Brighton; but tried Extracts

thing to mere love of novelty, and of wandering out of the prescribed road; something, also, to their intermixture of truth: and this latter point deserves more attentive consideration. The groundwork of a system of quackery will often be found in some error in the regular practitioners, detected and repaired; sometimes in some discovery which we have ourselves made, and which we ought to have carried out. The system of homoeopathy is mainly the offspring of our injudicious use of remedies on the side of excess. The Morrison pill is a mischievous application of Dr. Hamilton's views on the use of purgatives. Hydropathy is an exaggeration and extension of the beautiful principles unfolded by Dr. Curry, of Liverpool, which we have ourselves allowed to drop into neglect. "The cause of this fluctuation in medical opinion," Dr. Christison says, in his admirable article, Continued Fever, "is not very clear; but there can be no question, that the change was not made without sufficient reason." I must venture on this point to differ with Dr. Christison. The existence of a "sufficient reason" is not clear. Let us have the opinion of Dr. Pitcairne on the subject. In the Life of the late Sir Samuel Romilly occurs the following passage. "My little girl was last week seized with a very dangerous fever. Having read in Dr. Curry's book of the happy effects produced in many cases by the application of cold water in fever, I asked Dr. Pitcairne, who attended her, whether it might not be advisable to try it. He said he thought it certainly would; that it might be of great service, and could do no harm, but the prejudice in London against it was so strong, that he never ventured to recommend it." This strength of prejudice at the head quarters of English medicine possibly prevented the establishment of a hydropathic system in a modified and scientific form and extent among us. In estimating the claims of quackery, we should remember, that, however strong the love of marvellousness, the selfishness of man is a still stronger principle; and that he will not long indulge the former principle in matters of personal expediency, unless the latter has also some food.

Taraxaci, gr. xv. bis quotidie, which did him no good, but some harm; as it lessened his appetite.

He kept, however, the ground which he had gained, under the judicious management of Mr. Blizard, who relieved effectually the paroxysms of epigastric pain and irritation, to which he was still subject, by an occasional dose of Sodæ Sulphas in Pulna water. Finally the Carlsbad waters taken at Brighton in the next summer completed his cure. I have no exact account of the entire loss and gain of weight which Mr. A—— experienced, but it was very considerable; and what is remarkable, both were progressive, with halts indeed, but no retrogression, from the moment that each commenced. His emaciation and weakness in August 1831, were extreme, without pyrexia or any other symptom except pain.

It should be observed that he was, and is, a man of strong sense, and of a cool, firm, and patient character.

Mrs. S——, æt. 63, a lady of a spare habit and nervous temperament, who had lived very temperately, but had undergone much mental exhaustion, consulted me October 23, 1837, for pain which she had long felt at the epigastrium, particularly after eating. She looked very ill; her eyes were sunk, her person emaciated; pulse quick and nervous; tongue clean; no pain on pressure of the abdomen, which was neither tense nor distended; no confinement of bowels. She told me that she had sometimes found temporary relief from pills containing a small dose (gr. $\frac{1}{2}$) of calomel, with Ext. Colocynth Co. and Pil. Rhei. Co. The suffering occasioned by food taken into the stomach was evidently interfering with her nutrition. Her mind and external circumstances were at that time comfortable and easy.

She had left off vegetables. I recommended a softened and pulpy diet of farinaceous food, allowing her white meat and fish. I prescribed—

R. Pil. Hydrag. Chlorid Co. Pulv. Ipecac. Co. aa. \mathfrak{z} ss. in pil. xij. divis. i. o. n.

R. Pil. Rhei. Co. gr. ij.; Bismuth Tris-nitrat. gr. ij.; Opii. gr. $\frac{1}{2}$. quotidie ante prand.

R. Pil. Rhei. Co. \mathfrak{z} j.; Ext. Col. Co. Ext. Hyocyam. aa. gr. xvi. in pil. xij. divis. i. vel ij. p. r. n.

I learnt in some weeks afterwards,

that this plan had been eminently successful.

1841.—May 14th I was again consulted, the above symptoms having returned and resisted the repetition of the former plan of treatment. There was also pyrosis, but with little vomiting or nausea; bowels rather confined, some deficiency of bile, pains excessive after every kind of food at all times.

R. Opii Extract. gr. ij.; Aloes, Gentiane Extract. aa. \mathfrak{z} j.; Sapon. duræ, gr. x. Hyd. Chlorid. gr. iij.; in pil. xx. divis. I ter quotidie, that is, after each meal.

R. Hyd. Chlorid. gr. v.; Liniment. Camph. co. Liniment Sapon. co. aa. \mathfrak{z} ij.; pars dimidia Epigast. quotidie infricand.

R. Infus. Caryophyll. \mathfrak{z} iv.; Aquæ Pimentæ \mathfrak{z} iss.; Ammon. Sesquicarb. \mathfrak{z} ij.; Liqueur. Potassæ \mathfrak{z} i.; Træ. Humuli, \mathfrak{z} ij.; Syrup. \mathfrak{z} j.; M. ft. Mist. cujus sumantur coch. mag. ij. subinde.

This plan I learnt was entirely unsuccessful: I replaced it by the following:—

R. Pil. Hydrag. Chlorid. co. \mathfrak{z} iss.; Morphine Acetat. gr. iij. in Pil. xij. divis. I bis quotidie. Emplast. Belladonnæ regioni duodeni applicand.

My next and subsequent communications reported complete success in this plan of treatment, and in perseverance in the diet at first prescribed; which had not been discontinued. I have frequently since heard of the patient as having gained flesh, being enabled to eat more solid food, and enjoying a very competent degree of health.

M. R., the brother of the last patient, and of about the same age, has for many years suffered from gastrodynia coming on after taking food, at a distance of from two to six hours, often with excessive eructation and distension from wind; emaciation, apparently from the same cause as that of the last patient, namely, insufficient food; absence of pyrexia; no pain on pressure; a quick and regular pulse; a clean tongue; fæces good; bowels moved easily, and when they are moved strongly, aggravation of gastrodynia: he remembers that he has in some degree suffered in this way from his earliest youth. He has lived an active life of business, has been a moderate eater, but has taken alcoholic stimulants freely at different periods of his life. Stimulants of this kind, par-

ticularly hot whiskey and water, postpone the attack, but generally increase its severity. Alkalis mitigate it but slightly. At one period of this affection, and when it was in a state of great severity, œdema of the legs supervened in a high degree, and some ascites; and were entirely removed by extensive acupuncture of the legs and thighs. The discharge was very great; and the relief of gastrodynia, as well as of a sense of general oppression, was also great. This occurred four years ago, and since that time he has used the fixed alkalis largely with palliative effect. But the gastrodynia gained on him again, when I in 1842 ordered the use of muriate of morphia in quarter and half-grain doses nightly; and this has materially relieved the most oppressive part of the case, namely, sleeplessness occasioned by irritation and pain; added to the use of alkalis it has appeared to render a progressing disorder stationary. The total absence of pyrexia and also of symptoms of hepatic congestion in the last case, had rendered it apparently not inappropriate to a trial of preparations of iron. Accordingly, they were tried during his convalescence from the dropsy; but their effects were mischievous as far as they could be appreciated; apparently tending to reproduce the gastrodynia. The dropsy has never reappeared.

Of the three cases thus narrated, each certainly was tending to a fatal termination, when arrested by remedies, and in each there could be no doubt as to what remedy proved efficient, so far as effect was produced. In the first, mercurials profited; in the second, mercurials combined with a sedative; in the third, a sedative alone, or partially aided by habitual alkaline doses.

Of the remaining members of the family to which the two latter patients belong, one died, between his fiftieth and sixtieth year, from disease, apparently well marked, of the cardiac organs of the stomach, precluding at last all introduction of food. The other brother enjoys an entire immunity from affections of the digestive organs; but he is in an extreme degree crippled by gout.

[To be continued.]

ON THE PROGRESSIVE DEVELOPMENT OF THE OSSEOUS BODIES OF THE VERTEBRÆ AND STERNUM,

AND THE ORDER OF THE FORMATION AND
CONSOLIDATION OF EPIPHYSES, AS ILLUSTRATIONS
OF THE EFFECTS OF TENSION.*

By T. WILKINSON KING, F.R.C.S.E.

(For the Medical Gazette.)

IN physiology a knowledge of the mechanical agencies may fairly be esteemed the foundation of those inquiries which concern the less tangible objects of sense. The circulation being understood, humoralism becomes appreciable, and chemistry available; and after the study of the capillaries, the vital processes of nutrition become comparatively easy of comprehension. That pressure and tension affect the evolution of all parts, scarcely requires proof at this time, but it may be very acceptable to some to find fair illustration of the manner in which these forces seem to determine minute changes in our bodies; and the more so, since it becomes quite certain that remedial measures cannot be quite justly applied without reference to such principles of natural action.

After looking through some chapters of Burdach's Physiology, translated by Jourdan, I felt still more impressed with the general want of reflections of the kind I refer to. The formation of a cord of adhesion, or band of new ligament, or mass of osseous callus, the strengthening of an overstrained part, and the removal of disused parts, are properly among the concerns of daily practice. And it is but too plain in the writings of practitioners that views are still esteemed which encourage the attempt to cure hypertrophy (as of the heart), without regard to the fact that it may be an indispensable compensation; and which inculcate the foolish practices of relaxing ligaments to strengthen them, and of stretching muscles and tendons to weaken or elongate them. (See some elementary considerations on Irritation, by T. W. K. MED. GAZ. 1843.)

All bones have this in common:—A cartilage-like nidus in the beginning, having performed its specific office, as

* Vide a Notice on "Isolated Ossifications," T. W. K. in the Provincial Medical Journal, August 1843.

a mere solid, becomes the seat of earthy deposit. The precise site of this deposit seems to be determined by a certain excessive degree of pressure or tension, as in the centre of a cubical bone or of an epiphysis, or in the middle of a parietal or cylindrical bone. The continual depositions which succeed seem also strictly determined by the directions of pressure, or extension, or of both; but the formation of cancellus is most curious and instructive: it commences as the excavation of the growing nucleus, and proceeds *pari passu* with the formation of external layers of bone. Internal absorption thus attending external deposition, would seem positively to depend on the removal of pressure from the centre to the circumference.

These considerations are necessary to explain the natural and morbid changes of the internal structure of bones. Every bone has most to resist on its surface, and least internally. In proportion as the exterior is strained and excited, so is it nourished, so does it grow; while, as the inner parts are the more removed from physical tensions, they are carried off by absorption.

This applies to every fibre of cancellus; for it is only tension which maintains its nutrition and existence, and which originally caused it to survive the activity of absorption, a column having been spared at every individual spot where the need of resistance had been, in a manner, pre-indicated. Now, by attention to this principle of vital action, we may learn the peculiar distinctions of periosteum and endosteum. The first is for the habitual sustenance of the growing and most active part of every bone, while the so-called medullary membrane, so far as it is an internal periosteum, is only a source of nourishment to parts comparatively unexcited and vitally inactive. The internal and external diseases of bones are in strict accordance with the same rules; but it is essential to reflect upon another law, which is chiefly important with reference to particular morbid actions.

As the normal bone is forming, it consists of animal and earthy parts in nearly definite proportions; but in certain diseases either the cartilaginous or calcareous parts may be deficient. This involves the consideration of diathesis, or idiosyncrasy, or peculiarity of constitution.

We find cases in which the whole

osseous frame is in excess without abnormal proportions in its constituents; but we may also have the earthy matter alone defective, or in excess; and when the earths superabound in the blood (?) we see not only a morbid tendency to their deposition, but actually a proneness to inflammation of the vascular investments of the bones. It is when growth is ceasing, and in the most bony figures, and in the most active bones, that ossific formations are most likely to be excessive. In other cases we find the lime diminished in the system. The skeleton becomes flexible, united fractures become disunited, recent fractures are not duly repaired, and the fragments, or the whole bone, may be removed by absorption. Thus, then, we are to expect peculiar actions in the periosteum and endosteum, and also specific changes in those constitutions which are (so to speak) preternaturally ossific, or the reverse.

Of course, also, the age of the individual materially affects the local and general states; and peculiarities of these kinds have, no doubt, attended the results of the various experimenters, some of whom have found more reproduction of bone in young animals—even where the bone has been deprived of blood, excepting through very partial channels—than they could account for.

The distinctions between periosteum and endosteum are rather those of degree than of kind. The active use of the substance of the condyles is attended with equal nutrition, whilst the periosteum here has directly to nourish only thin and feeble layers of bone. In such parts, moreover, nutrition is more dependent on extensions; in the shaft of the femur the reverse is the case. I have elsewhere endeavoured to show,* that granulation, or any vascular surface adhering to vascular bone, is what constitutes periosteum; and that such is the efficient and only specific source of osseous formation.

The first vertebral ossicle seen with the naked eye is in the body of the 10th or 11th dorsal vertebra; after this, the next adjoining, above and below; and so all the rest successively appear;—and while the first keeps the lead in point of size, the most remote are long the least in size. Each ossicle seems

* See accounts of the union of bone, in the Cyclopædia of Surgery, article *Fracture*.

to be a symmetrical flat oval, with rounded edges, a minutely spongy surface, and coarsely reticular interior. After about the third month, the first formed bone, increasing in dimensions, begins to assume a new form; its anterior edge is divided by a slight transverse fissure—that is, it becomes double by the development of a lip above and below. The like takes place posteriorly also, and the sulci become deeper and deeper as the bone grows, until about the period of birth.

The sulci are developed in adjacent bones in the same order of succession as the bones appear in, but are scarcely to be seen in the cervical or sacral ossicles. The first formed is always the largest, and the last to be filled up. The last formed are the first to disappear.* Towards the end of the third month after birth, the anterior face of the body of every vertebra is a tolerably flat surface, and the posterior fissures or sulci are little more than wide apertures for vessels.

Mr. John Birkitt, demonstrator of anatomy at Guy's Hospital, handed me the following abstract from Weber's *Handbuch der Anatomie, Osteologia*, p. 227:—

"According to my observations—
1. The bodies of all the vertebræ, which even for a long time after birth are separated from the arches, are formed from at first four pairs, or eight osseous centres: of these, four lie near each other above, four near one another below.

"In a fœtus of from four to seven months we may often therefore perceive distinctly a horizontal division of the bodies of the vertebræ into a superior and inferior half; also, the perpendicular division of the vertebræ in the middle line of the body."

"The time of the origin and the consolidation of these different bony points and pieces of the bodies of the vertebræ is variable." "The first and second cervical vertebræ, and the sacral vertebræ, by virtue of their peculiar formation, form an exception to the general rule."

Now I have found that the tissues become so transparent by simple maceration, that, as far as the naked eye can go, it is impossible for me not to

* There seems to be some exception to this last statement; perhaps the middle dorsal sulci may be the last to disappear.

reject these statements. See a series of minute fetal spines in Guy's Hospital Museum.

It may be thought that such changes as those I have related are but of trifling import to the medical physiologist; and I am ready at once to admit as much, provided his attainments have already placed him above the need of rudimentary reflections on the influence of tension in the healthy and morbid processes of the human body; for such considerations are indispensable to the right management of deformities, and even of every reparative process.

It strikes me as a clear and complete explanation of the vertebral ridges, and of their origin and decline, as above described, to represent them as condyles formed where ligament is inserted, and where the flexions and extensions of uterine life determine repeated and excessive strainings. When the spine comes to be an organ of support, when it has great vertical forces to resist, then columnar fibres fill up the transverse sulci. Subsequent morbid ankylosis is but a modified repetition of the fetal ridges.

In the article "Fracture," in the *Cyclopædia of Surgery* (p. 273), I have made the following remark.

"It is the presence of bone in the circulating system which leads to its massive formation. In proof of this, consider the stag's horn. The cause which fixes the precise spots of incipient (fœtal) ossification is, I conceive, specific. The event takes place in a solid nidus, at a point where many convergent forces or pressures are concentrated. The continuance of ossification (being, as it were, a columnar growth against gravity) follows a similar rule, for it is a deposition where pressure is greatest; and whether we regard the order in which the nuclei of all the bones begin, or the order of rapidity with which each one grows, the activity is evidently in dependence on the tension of the parts. The form of every bone, and process of bone, and even the arrangement of every fibre of cancellus, seems to me to be regulated by the above principle."

"To illustrate this opinion extensively, would be here out of place, though it is a valuable consideration, if it be applicable to all other tissues, as I do not doubt it to be. The tension

or excitements of a part are equal to its uses and its wants: the supply, in kind, in manner, and in site, to its minutest point, is determined by the tensions; which *tensions* declining, atrophy begins.

"That much depends on tension seems corroborated by the final remark, that when tension is removed from the centre it becomes absorbed, which explains the excavation of bone*, the course of simple atrophy, and the modelling of definitive callus; while it cannot be too strongly enforced, that the mere disproportionate weakness of a part leads to augmented nutrition in that part (if nutritive material fail not), whether it be membrane, muscle, or bone."

M. Meckel (Manuel d'Anatomie: du Femur) remarks, "Sa courbure ne commence à devenir apparente que vers la fin de la première année, et elle augmente ensuite peu à peu. En général, elle est plus considérable chez l'homme que chez la femme."

Here, superincumbent weight, muscular and ligamentous compressions, and extensions direct and indirect, partial or more general, are determining growth in various degrees and directions externally, while loss of tension within guides the course of excavation.

The growth of ossicles in the cartilaginous sternum seems to be guided by the same law as that which affects the vertebræ. The cordiform bone has normally one bony point placed centrally between six or seven points of pressure. If two points ossify, their position still seems guided by a like

rule; they are placed one above the other in the median line.

In the second bone of the sternum we usually find an ossicle in two mesian points, each between the articulations of four rib-cartilages.

All the bones are first spherical, and next round flattened cakes. After this the squaring (growth towards four chief points of pressure), throwing up of prominences, and rounding off of surfaces, is, as before stated, evidently enough in accordance with the rule manifest in all parts—that every point becomes strengthened or atrophied in proportion as it becomes strained or disused; i. e., of course, so long as the nutrient acts of the body are duly performed. (See a numerous progressive series of fetal sternums in Guy's Hospital Museum.)

The order in which the principal epiphyses of bones ossify and become consolidated to their main shafts, I find, also, to be pretty strictly in accordance with the physical tensions to which they are, in point of time, successively subjected; and I think it will appear (almost without other comment than the following table) that the full development of various parts, more or less connected with them, depends on the very same influence.

Before birth, betwixt the sixth and the tenth week, the cylinders appear in the following order:—

Clavis, humerus, ulna, radius, femur, tibia, fibula, head of tibia.

At birth a point appears between the condyles of the femur, in the external condyle of humerus, in the lower end of tibia, and in the two ends of fibula.

The subsequent ossicles appear thus:—

About the 3d month after birth, the Head of humerus and femur.

"	"	"	"	"	Patella.
"	12th	"	"	"	Great tuber humeri, and then inner condyle.
"	2d year	"	"	"	Lower end of radius.
"	4th	"	"	"	Greater trochanter, and then lesser.
"	6th	"	"	"	Lower end of ulna, and then upper.
"	7th	"	"	"	Upper end of radius.

The bony unions of epiphyses occur thus:—

Long before puberty Head of radius, Inner condyle of humerus.

External ditto. (?)

About puberty The Lower end of Tibia, and then the Upper.

The Upper " Ulna, " " Lower.

A little after puberty The Lower end of Fibula, and then the Upper.

* If the initiative steps of excavation are guided as above, the commencement of medullary membrane and its particular artery is similarly regulated. The direction in which the ossicle now proceeds to develop itself settles for ever

that of the nutritive foramen. Subsequent mechanical causes determine the unequal growth of parts of bones, and with them the various relative sites of nutritive foramina.

REMOVAL OF STONE WITHOUT INCISION OF THE PROSTATE. 7

Some time after puberty . . . The Head and Tuber of humerus unite, and then join the shaft.

Now, too, the femur is joined successively by trochanter minor, caput, trochanter major, and lower end.

Long after puberty The Lower end of radius joins its shaft.

The above facts are chiefly from Meckel, who follows and corrects Albinus. I have omitted some statements, and might perhaps have omitted others, without detriment to the object I have in view.

It is apparent that the bony development of the arm, advancing rapidly before birth, is surpassed by that of the leg after birth, when the last becomes most subjected to strain, &c. The ulna first grows upwards, and then elongates downwards; with the humerus it is just the reverse.

The seeming irregularity of the periods at which different epiphyses

are consolidated is, I think, reduced to a systematic principle by taking into consideration the breadth of surface to be consolidated, or rather that over which the effect of pressure is diffused, and by which, as it were, a certain measure of pressure is diluted or subdivided.

Thus, I make pressure the general determining cause, and breadth of surface a modifying cause. It is needless to shew the application of this theory; and the final acceptance of it may well be left to depend on correlative reflections.

36, Bedford Square, April 1844.

REMOVAL OF STONE WITHOUT INCISION OF THE PROSTATE.

CASE OF LITHECTASY,

IN A LETTER FROM J. G. WRIGHT, M.D.
MALTON, TO R. WILLIS, M.D. LONDON.

(For the Medical Gazette.)

THE following case, in which a stone, weighing as nearly as possible two ounces troy, was successfully removed from the bladder by the gradual dilatation of its neck and of the prostate gland, without incision of these parts, is so interesting and important, that I have much pleasure in having obtained Dr. Wright's consent to make it known to the profession. I had been informed a few weeks ago, by a gentleman residing near York, who consulted me professionally, that Dr. Wright, of Malton, had lately done a new operation for stone, by a process of gradual dilatation, and that the subject of it had made a rapid and complete recovery. On this I addressed myself to Dr. Wright, and in the course of a few days afterwards received the following excellent letter:—

Malton, May 30, 1843.

My dear sir,—It affords me great pleasure to confirm the account of the case of Lithectasy with which you were accidentally made acquainted, and to furnish you with some additional par-

ticulars respecting it. It is one of the results of the publication of your excellent little work, "On the Treatment of Stone by Medical and Mechanical Means," and I believe it will exert some influence in establishing the operation you advocate so warmly.

The subject of the operation was a Mr. John Walton, aged 60, a farmer and bricklayer, living at Askham Richard, near York. He first consulted me in September last: he had laboured under symptoms of stone for at least three years. On sounding him, a stone, apparently of considerable size, was detected. The patient strongly urged me to attempt to remove it by the lithotrity, which he had heard of my having successfully used on a former occasion. To this I firmly objected, on these grounds:—1st, The urethra was unusually small; 2d, The bladder was extremely irritable, and appeared very much contracted; 3d, The stone was evidently a large one, and, from the sound elicited when it was struck, we imagined it was very hard,—a conjecture which proved to be quite correct.

On reading an account of the operation proposed in your work on Stone a few months previously, I was fully convinced of its superiority over the established modes of removing calculi; and I determined to test it on the first case that presented itself. In this instance, however, I had no alternative, for the reasons stated I would not at

tempt lithotrity, and the patient expressed a determination to die with the stone in the bladder rather than submit to the lateral operation.

The operation was commenced on the 27th of September, 1832. I was assisted throughout the whole of the treatment by the zealous and efficient co-operation of one of the surgeons resident here, Dr. Esley. The rectum having been cleared out by an injection, and a staff introduced into the bladder, the patient was placed on the bed, in the position for lithotomy. An incision having been made between the scrotum and the verge of the anus, the groove of the staff was felt for, and an opening a few lines in extent was made into the membranous portion of the urethra, care being taken to avoid the bulb. The first difficulty we encountered was in the attempt to introduce the dilator. The urethra would not admit a staff larger than a No. 10 catheter, and the groove in this instrument only partially received the extremity of the dilator; so that when an attempt was made to glide the latter into the bladder, we found that the urethra would not receive at once the staff and the dilator. The staff was therefore withdrawn, and the dilator introduced alone. It passed readily enough into the urethra up to the point where the silk bag and bladder are attached to the tube, at which part of the instrument there is naturally a considerable projection. As there was no possibility of passing it farther without unjustifiable violence, we set about effecting the dilatation of the membranous portion of the urethra by a succession of bougies, which was not accomplished without some loss of time, and some suffering to the patient. We then contented ourselves with the simple introduction of the dilator, which was now effected without difficulty, resolving to wait before proceeding to any further dilatation till the irritation occasioned by the bougies had subsided. It was some days, during which the urine passed through the tube of the dilator, before it was thought prudent to proceed with the operation.

Sept. 30th.—A little fluid was thrown into the instrument, for the purpose of commencing the dilatation; but it most provokingly escaped as fast as it was injected. We were not long in detect-

ing the cause: the bladder had become putrid from the warmth and moisture to which it had been so long exposed. Of course we were compelled to remove the instrument, and fit it up with a fresh bladder: after which it was reinserted, but not without much difficulty; and the patient complained so much of the irritable condition of the parts, that we were again compelled most reluctantly to discontinue the dilatation.

Oct. 1st.—The patient has passed a very uneasy night; this morning the tongue is dry, and brown at the centre, there is much thirst, and complete loss of appetite; the abdomen is greatly distended, owing probably to his not having had an evacuation for some days; the pulse is not accelerated. He was ordered to have an injection.

The enema answered but indifferently. In the evening he was sick and vomited. The tongue continued dry and brown; the abdomen was tympanitic, and as much distended as before the injection was used; there was some flatulence of stomach, and occasional hiccup. The pulse was extremely feeble, and the countenance anxious, with great loss of strength and depression of spirits. These symptoms occasioned us much uneasiness. You will remark, however, that hitherto, in consequence of the constitutional disturbance, and the derangement of the instrument, we had not made any decided efforts to dilate, and we agreed not to do so till there was some marked improvement in the general state of the patient.

6th.—No progress was made last week. During the early part of the week we waited for some abatement of the constitutional disturbance, and during the latter part for a dilator, for which we had written to London.

8th.—The general health of the patient is now pretty good, and the bladder and urethra have completely lost their irritability. We have now the advantage of possessing two instruments, both in excellent order.

9th.—Yesterday and to-day, for the first time, the dilatation has gone on quite satisfactorily. We have only proceeded very slowly, however, and with extreme caution.

10th.—The dilatation now progresses very rapidly, and every thing promises

a favourable result. The patient has no pain, except in the glans penis, and that is not severe.

11th.—The patient had a copious evacuation from the bowels during the night. The urethra having been now dilated to as great an extent as the instrument would allow, an effort was made to extract the stone. It was seized with the lithotomy forceps, but it was discovered to be too large to be removed entire, without using more violence than was thought prudent or safe. We had taken the precaution to have in readiness the lithotrite of Professor Ferguson, with which the outer layers of the stone were broken off, and removed piecemeal.

The breaking up of the stone was the most difficult part of the operation. The lithotrite can only be used with facility when the bladder is moderately distended, so as to allow of its being freely opened and turned. In the present instance, of course no water could be retained in the bladder, which was firmly contracted upon the stone. By gentle and persevering efforts, however, the outer layers were at length removed, and the stone having been thus greatly reduced in size, the remaining portion was grasped by the lithotomy forceps, and brought away. The central stone, with as many of the fragments as could be collected, weighed a little short of two ounces troy. The patient was perfectly easy the moment the operation was completed; he soon afterwards fell into a sound sleep. In the evening there was some little excitement, but not the slightest pain or uneasiness. I should have stated, that a tube was inserted, as after the lateral operation.

After the lapse of some days the tube was removed, when we were delighted to find that the patient had regained a perfect control over the sphincter—the urine was retained without difficulty. In order to facilitate the escape of any fragments which might still remain in the bladder, the wound was kept open by the occasional introduction of a bougie. A week after the operation had been completed, the bladder was carefully sounded when moderately distended with urine; and we fully satisfied ourselves that no fragments remained. Not one unfavourable symptom followed the operation.

The difficulty and loss of time oc-

curing in this my first attempt at lithectomy I have been careful not to conceal, as I am convinced they might be avoided on a future occasion. Allow me briefly to allude to the causes of our embarrassments.

1st. The parts were in an unusually irritable condition when the operation was performed. In other words, the patient was suffering from a paroxysm of stone; a circumstance which we were only made acquainted with some time afterwards, as the patient most injudiciously concealed it from us, from a desire, natural enough perhaps, to be relieved from his torture as speedily as possible.

2ndly. The groove of the staff was too small in proportion to the size of the extremity of the dilator.

3dly. The dilator might have been greatly improved. The extremity of the tube was too thick, and the projection occasioned by the attachment of the bladder and silk bag greater than necessary.

4thly. The lithotrite cannot be used satisfactorily in an empty bladder, but I have somewhere seen a pair of lithotomy forceps with a drill passing through the joint, which I conceive would accomplish every thing desired.

Lastly, would it not be better to make the incision in front of, or anterior to the bulb, where the canal is so superficial that it could be opened by a mere scratch? It certainly requires no formidable incision to reach the membranous portion; still, it must be of some depth, and it occurs to me as being just possible that on introducing the dilator its extremity might be carried past the opening in the urethra into the surrounding cellular tissue. I imagine the bulbous portion would be dilated as easily as the membranous part of the urethra.

No greater boon has, I conceive, been conferred on the profession for many years, than the proposal, or revival, of an operation which renders the treatment of one of the most formidable of diseases comparatively so simple and so safe. I shall ever feel most grateful for the information derived from your little work. I am happy to have had so early an opportunity of practically testing its most valuable suggestion.—

Believe me, dear Sir, to be

Yours very sincerely,

J. G. WRIGHT.

tempt lithotripsy, and the patient expressed a determination to die with the stone in the bladder rather than submit to the lateral operation.

The operation was commenced on the 27th of September, 1832. I was assisted throughout the whole of the treatment by the zealous and efficient co-operation of one of the surgeons resident here, Dr. Esley. The rectum having been cleared out by an injection, and a staff introduced into the bladder, the patient was placed on the bed, in the position for lithotomy. An incision having been made between the scrotum and the verge of the anus, the groove of the staff was felt for, and an opening a few lines in extent was made into the membranous portion of the urethra, care being taken to avoid the bulb. The first difficulty we encountered was in the attempt to introduce the dilator. The urethra would not admit a staff larger than a No. 10 catheter, and the groove in this instrument only partially received the extremity of the dilator; so that when an attempt was made to glide the latter into the bladder, we found that the urethra would not receive at once the staff and the dilator. The staff was therefore withdrawn, and the dilator introduced alone. It passed readily enough into the urethra up to the point where the silk bag and bladder are attached to the tube, at which part of the instrument there is naturally a considerable projection. As there was no possibility of passing it farther without unjustifiable violence, we set about effecting the dilatation of the membranous portion of the urethra by a succession of bougies, which was not accomplished without some loss of time, and some suffering to the patient. We then contented ourselves with the simple introduction of the dilator, which was now effected without difficulty, resolving to wait before proceeding to any further dilatation till the irritation occasioned by the bougies had subsided. It was some days, during which the urine passed through the tube of the dilator, before it was thought prudent to proceed with the operation.

Sept. 30th.—A little fluid was thrown into the instrument, for the purpose of commencing the dilatation; but it most provokingly escaped as fast as it was injected. We were not long in detect-

ing the cause: the bladder had become putrid from the warmth and moisture to which it had been so long exposed. I shall ever feel most grateful for the information derived from your little work. I am happy to have had so early an opportunity of practically testing its most valuable suggestion.—

Believe me, dear Sir, to be

Yours very sincerely,

J. G. WRIGHT.

Observations on the foregoing Case.

When we reflect on the particulars so well and fully stated in the preceding history, it seems certain that the loss of time, and through this, the somewhat serious febrile attack which the patient suffered, may be attributed to defects of apparatus. Had the operation proceeded at once, it seems certain that the patient would have escaped with no greater amount of suffering than he experienced between the actual beginning and the ending of the process of dilatation and the extraction of the stone, that is, between the 9th and the 11th October. The external incision was made, and a passage obtained into the membranous part of the urethra, on the 27th September; the patient did not become unwell until the night between the 30th September and 1st of October. With sufficient apparatus, there was therefore ample time to have accomplished the dilatation and removed the stone, and as there is infinitely less risk of exciting irritation by the use of the fluid pressure-dilator, than of bougies, I believe that the business might have been achieved without the patient having suffered any the slightest constitutional disturbance. It is impossible not to admire Dr. Wright's very judicious management of the patient in the critical circumstances in which he was placed, through no fault or inadvertence of his own, but solely through the clumsiness and imperfection of his instrument. But in entering upon new courses there are always many unforeseen difficulties to be encountered and overcome, which do not meet the traveller upon the beaten track. From this time forward I apprehend that lithectasy will become an easy operation. The surgeon has now had leisure to familiarize his mind with the details of the procedure, to see clearly all that is wanted to bring the operation to a successful issue; and the instrument-maker now knows exactly what the surgeon requires on his part in the way of tools. Different cases will doubtless require somewhat modified procedures: the extent and kind of external incision would not be the same in reference to small and to large stones. Where the stone was small or of moderate dimensions, between the size of a cherry and a walnut, a cut in the mesial line would suffice; with a stone the size of a hen's or a turkey's egg, it

might be advisable as suggested to me by Professor Fergusson of King's College, to make a triangular flap by carrying from the lower point of the incision in the line of the raphe, another short one on either side towards the tuberosity of the ischium, in front of the anus. I leave this to practical surgeons; for my own part, I feel averse to any extensive external wound in performing lithectasy; I should always be disposed to break down the stone, as Dr. Wright did, where it exceeded an inch or an inch and a half in diameter, although I am persuaded that with patience no difficulty would be experienced in procuring an outlet for a stone of two inches diameter, or more.) I fully agree with Dr. Wright in what he says with reference to entering the urethra on this side of the bulb. The division of the bulb is of no moment; in many urethras it is but very little if of any greater diameter than the rest of the corpus spongiosum urethræ, and has attracted particular attention solely from its being the commencement of that portion of the erectile tissue of the male organ.

R. WILLIS.

REPORT ON THE PRESENT
STATE OF KNOWLEDGE OF THE
NATURE OF INFLAMMATION.*

By T. WHARTON JONES, F.R.S.

Lecturer on Anatomy, Physiology, and Pathology at the Charing-Cross Hospital; Corresponding Member of the Imperial and Royal Society of Physicians and Surgeons of Vienna, &c. &c.

(Abstract prepared by the Author for the Medical Gazette.)

RETARDATION of the flow of blood in the small vessels, coincident with dilatation of their caliber, and at last accumulation and stagnation of the blood-corpuscles in the vessels, constitute the first phenomena constantly appreciable by the microscope in the inflammatory process, as observed in the frog. The macroscopical phenomena of inflammation in man seem to warrant the inference that the microscopical ones are essentially the same in him as in the inferior animal. The explanation of

* British and Foreign Review, No. xxxiv.

these phenomena, therefore—their sequence and relations—is justly considered as the key of the whole theory of inflammation.

Is the dilatation of the small vessels primary, and the retardation of the flow of blood in them secondary, or is the contrary the case? That dilatation is primary, and retardation of the flow of the blood the necessary physical result of the preceding dilatation, is maintained by most recent authors. And this opinion is to be considered as just; but it does not embrace the whole truth, which appears to be this:—Dilatation is primary; but the retardation in the flow of the blood being greater than the dilatation will physically account for, can be, in part only, its physical effect. The other cause in operation is the same as that which at last determines the accumulation and stagnation of the blood, as will be explained below. By the accumulation of the blood, however, there is a secondary dilatation of the vessels—a dilatation from distension, but which more particularly implicates the capillaries—perhaps is the sole dilatation of which the capillaries proper are the seat.

Having thus determined that there is a primary dilatation of the vessels, the next subject of inquiry is as to the nature of the dilatation. Does it depend on an active state, or on a state of relaxation of the walls of the vessels? The prejudice that inflammation is a state of increased action of *all* the parts concerned, which has led some (justly believing that constriction is the active state of the vessels) to maintain that the vessels are constricted in inflammation, has led others (knowing that the vessels are really dilated in inflammation) to maintain that their dilatation is an active state.

But the conclusion to which every thing leads us is that which was first suggested by Vacca, and in corroboration of which microscopical observations were first adduced by Wilson Philip, and are now admitted by most authors on the subject, that the dilatation of the arteries in inflammation is a state of relaxation or paralysis, not of activity. The next inquiry is as to whether the capillaries and venous radicles have contractile coats, and are therefore subject to dilatation from relaxation.

Though constriction and dilatation of the capillaries and radicles of the veins are said to take place as well as constriction and dilatation of the small arteries, it is proper to observe that it is the latter alone which are seen under the microscope to be the seat of such marked constriction and dilatation of their caliber, as appear to be owing to an action of their coats of the nature of vital contractility. So marked is the difference in this respect between the small arteries and the capillaries, that whilst the caliber of the artery may be observed to become almost wholly obliterated for the time by contraction of its walls throughout the whole extent of the part of the vessel under observation, or at intervals to present the appearance of a series of strictures,—a varicose appearance, as Wedemeyer expresses it, the capillaries into which it opens continue to preserve their caliber little or not at all changed.

Not being satisfied that the capillaries and radicles of the veins have contractile walls, and to admit, therefore, primary dilatation from relaxation, Mr. Jones is disposed to believe that dilatation of the capillaries and radicles of the veins is secondary to the retardation of the flow of blood in the arteries, and is owing to distension from the accumulating blood.

It being thus certain, to use the words of Dr. Alison, that during the whole time when inflammation, and the effusion consequent on it, are most evidently going on, the condition of all the vessels (possessing contractile walls) leading to and passing through an inflamed part, is not one of contraction but of relaxation; the question before us, viz. whether the phenomena of inflammation can be explained by the alteration of the *vital powers of the vessels* in which the blood moves, is, Dr. Alison thinks, narrowed to this:—Does that state of relaxation afford a sufficient explanation of the changes which take place in the inflamed parts?

The effect of relaxation of the vessels is dilatation, and the effect of dilatation is retardation of the flow of blood; though, as has been said, and as will be shown below, the whole amount of retardation which takes place is not alone the direct physical effect of the dilatation. But putting this question aside for the present, let it be inquired what

out by Emmert, speak strongly for this coincidence.

Before entering upon an exposition of the theory which appears to the author of this Report to harmonize most completely with all the facts of the case, he postulates the following propositions, delaying what proofs may further be required to support them.

1st. That the constriction and dilatation of the caliber of the small arteries at least, if not of the capillaries, is owing to contraction and relaxation of their walls in virtue of the vital endowment of contractility or tonicity which they possess; the exercise of which contractility is dependent on nervous influence.

2d. That the constant moderate exercise of this endowment on which the ordinary state of tone of the vessels depends, is determined by the constant moderate discharge of nervous influence.

3d. That whilst a greater state of contraction of the vessels than ordinary is owing to an increased discharge of nervous influence, the relaxation, atony, or paralysis of the walls of the vessels on which their dilatation depends, is owing to the suspension of nervous influence.

4th. That the relaxation with dilatation of the vessels from suspension of nervous influence, is the precursor of the retarded flow of blood and stagnation.

How the suspension of nervous influence from the walls of the small arteries on which their dilatation depends is produced, involves the question of the mode of operation of the exciting cause of inflammation. To this attention will by and by be directed. At present, inquiry has to be made how the suspension of nervous influence from the small arteries, and consequent relaxation and dilatation of these vessels, are connected with the retardation of the blood and subsequent stagnation.

In entering upon this inquiry, Mr. Jones in the first place remarks that it appears evident that the agglomeration of the red corpuscles of newly abstracted blood is owing to their being withdrawn from some influence under which they were held while in the body, an influence which keeps down the tendency to aggregate.

The circumstance that the red corpuscles of extravasated blood aggre-

gate, shows that that influence is exerted on the blood, in no part of the body, save within the vessels. But the circumstance that the red corpuscles do aggregate in inflammation within the vessels, shows that the influence here spoken of may cease to be exerted on the blood even there.

Now it has been seen that it is not when the vessels are constricted, and consequently when they are receiving nervous influence, but when they are dilated, and when consequently there is a suspension of nervous influence from them, that aggregation of the red corpuscles and consequent stagnation of blood takes place in the capillaries. The natural inference from this is, that the influence which keeps down the tendency of the red corpuscles to aggregate is communicated to them by the nerves which accompany the small vessels, arteries as well as capillaries, as the blood passes through them.

When, then, the nervous influence is withdrawn from the small arteries, and they have in consequence become relaxed and dilated, and when any nervous influence which may naturally be exerted on the capillaries is from the same cause withdrawn, the blood flows slowly through the dilated small arteries into the capillaries, as into an indifferent cavity, and is in the same condition as regards tendency of the red corpuscles to aggregate, as is blood when newly drawn from the body, or when extravasated.

Aggregation of the red corpuscles accordingly takes place, some at the same time adhering to the walls of the vessels. This latter phenomenon is to be attributed in like manner to the suspension of nervous influence from the small vessels. For it is to be observed that the circumstances of the red corpuscles keeping together in the axis of the stream, and aloof from the walls of the vessels in the natural state of the circulation, may be accounted for with Mr. Martyn Roberts by the nervous influence annulling the attraction of adhesion, or causing a repulsion between the red corpuscles and walls of the vessels, at the same time that it does so among the red corpuscles themselves. The suspension of the repulsion between the red corpuscles and walls of the vessels, also allows the entrance of red corpuscles in numbers, into the very small vessels into which

they before occasionally and few in number only entered.

The retarded flow of blood which precedes the stagnation can be admitted to be in part only the physical effect of the dilatation of the paralysed vessels,—it is greater than the dilatation appears physically to account for. The other cause appears, from what has been above said, to be the commencing attraction among, and the agglomeration of, the red corpuscles, as also the commencing attraction between them and the walls of their containing vessels.

Mode of action of the exciting Cause of Inflammation.

That the exciting cause of inflammation acts through the nervous system had been supposed by many, and had indeed been acknowledged as certain in the case of inflammation of internal organs from cold; but no detailed explanation was attempted of the nature of the part which the nervous system plays until recently. For this pathology is indebted to Henle* and Stilling†

Though explaining differently its mode of action, Mr. J. recognizes with Billing and Henle, as the essential condition of stagnation of the blood in inflammation, suspension of nervous influence from the small vessels, with consequent relaxation of their coats, and dilatation of their calibers.

The theory which Henle, by his physiological investigation of the subject, has been led to form of the mode in which the exciting cause of inflammation determines the suspension of nervous influence from the small vessels on which their relaxation and dilatation depend, is this:—

The exciting cause, of what nature soever it be, whether external or internal, acts primarily on sensitive nerves, exalting their activity. The motor nerves of the vessels which have sympathetical relations with the excited sensitive nerves, are secondarily affected. But this affection of the motor nerves of the vessels, which supervenes by reflex action on the excitement of the sensitive nerves, is not

a corresponding state of excitement, but an opposite one of depression, of suspension of action, of paralysis.

This form of sympathy, in which the state of excitement of one nerve determines depression of another, Henle calls *antagonism*; the name of *sympathy* in a restricted sense being retained for that form in which a state of activity of one nerve is called forth by a corresponding state of another. This latter form is more common in the domain of the cerebro-spinal system; the former in the domain of the ganglionic system, the source of the nerves of the vessels.

Sometimes, however, sympathy is exemplified in the vessels by constriction supervening on irritation and preceding dilatation. But in most cases relaxation and dilatation of the vessels from suspension of nervous influence, are the primary effect of an irritation, no matter whether it have been violent or slight. Hence Henle contends that the relaxation of the vessels on which their dilatation depends cannot be a mere consequence of their exhaustion from previous action, as has been suggested by Alison (p. 117) and Billing, but can only be antagonistic. Into this, however, it is not necessary to enter; for, provided suspension of nervous influence and consequent dilatation of the vessels do take place, it is indifferent for the theory of the proximate cause of inflammation above expounded, whether that state of the vessels be the result of antagonism, or of exhaustion succeeding a state of activity induced by sympathy.

In regard to the inflammation of an organ which occurs after section of some part of the sympathetic, Stilling declares it to be owing simply to paralysis of the walls of the vessels, from destruction of the source whence their motor nerves are derived. And this, taken in conjunction with the theory of the proximate cause of inflammation above enunciated, appears to be the true and natural explanation.

The inflammation of the eye after section of the fifth pair, and of the lungs and stomach after section of the par vagum, Stilling also holds to be the effect of paralysis, but determined in the following indirect manner:—He supposes that a reflex action from sensitive nerves to the nerves of vessels is

* Pathologische Untersuchungen, 1840, and also "Bericht," ut supra.

† Physiologische, pathologische und medicinisch-praktische Untersuchungen über die Spinal-irritation, 1840.

constantly going on, and is a necessary condition to the activity of the vessels. When, therefore, the sensitive nerves are cut, a suspension of this reflex action takes place; the consequence of which is paralysis of the nerves of the vessels,

Henle objects to this view of Stilling—and the objection is also applicable to Alison's—that were the integrity of sensitive nerves a *conditio sine qua non* for the normal function of vessels, loss of sensibility must in every instance be followed by stagnation of the circulation, which is not the case; for there are anæsthesiæ in which the circulation in the part goes on: when the nerves in the leg of the frog are cut, for example, the circulation nevertheless continues.

According to Henle, the stagnation of blood which takes place after section of sensitive nerves, the fifth pair, the par vagum, &c., belongs to a category, including those stagnations, along with those which occur after section of branches of the sympathetic. It must only be granted that sympathetic turges, or nerves of vessels, are mixed with those so-called sensitive nerves. In paralysis from affection of the central ends of these nerves, the vessels are not necessarily implicated, and therefore remain active; in the section of the nerves of the extremities, as in Hausmann's cases, they were not injured, because they accompany the vessels.

According to Magendie, the inflammatory symptoms in the eye are more violent after section of the first branch of the fifth than after section of the trunk above the ganglion of Gasser. This fact, which is inexplicable according to Stilling's view, is, Henle thinks, easily intelligible according to his;—for in the first case, all the nerves of the vessels, including those contributed by the sympathetic, are cut; in the second case, probably only a small number, which are from the first mingled with the trigeminus.

The inflammation which sometimes accompanies spinal irritation, or neuralgia, Stilling explains in the same way as he does that which results from the section of the fifth pair; he

supposes that in neuralgia the sensitive nerves are in a state of paralysis. Henle maintains the opposite, and explains the inflammation on his principle of antagonism, above mentioned, thus:—Neuralgia being a state of excitement of a sensitive nerve, determines antagonistic paralysis of the motor nerves of the vessels of the part, whence relaxation of their walls and dilatation of their caliber.

Exudation.

Immediately after or during the stagnation of the blood, exudation commences. From being at first serous, the exuded fluid comes at last to be pure plasma, or at least a fluid containing a greater or less quantity of fibrin.

None of the corpuscles of the blood pass out along with the exuded fluid so long as the vessels are entire. But it is often observed that at certain points the walls of the vessels in which the blood was stagnated have given way, and permitted an extravasation of both red and colourless corpuscles.

With exudation is completed the inflammatory process, properly so called.

To the Editor of the Medical Gazette.

SIR,—In looking into the *Physiologische und Anthropologische Chemie* of the late Dr. J. F. Simon, (Berlin, 1842) which has now for the first time come into my hands, I find a somewhat similar opinion entertained in regard to the production of the fibrine of the blood, as that which I advocated in my *Observations on the Blood*, in the *British and Foreign Review* for Oct. 1842, and to which I again refer in my *Report on Inflammation*, just published. Dr. Simon's work bearing date April 1842, he of course preceded me, and I am anxious to make this acknowledgment of his priority. Dr. Simon in his preface, states, that he had already communicated his views regarding the production of fibrine, in the autumn of 1840, at the meeting of Naturalists held at Erlangen.

I am, sir,
Your obedient servant,
T. WHARTON JONES.

London, April 12th, 1844.

ARE PHYSICIANS COMPETENT AUTHORITIES
OR NOT ON
ANATOMICAL QUESTIONS?

To the Editor of the Medical Gazette.

SIR,

MY attention has just been arrested by a communication to you in your number of March 22d, by Mr. Earle, of Cheltenham, on the subject of Inflammation. I cannot help thinking that Mr. Earle in that communication has been greatly wanting in courtesy to Dr. Copland, and that he also very wantonly and wrongfully casts a slur upon the branch of the profession which has hitherto maintained, and deservedly maintained, the highest place in the general eye, for its science and practical skill—that of the physician. Mr. Earle ventures to tell us, that all who have adopted a certain opinion, which he disapproves, were “Physicians; that is to say, men who cannot be received as authorities on an anatomical question.” And wherefore not, Mr. Earle? Who was William Harvey, or Albert Haller, or Alexander Monro, or William Hunter? Perhaps Mr. Earle wots not of these immortal names, or that their owners in their lives were all physicians. Without the last mentioned, the glory and honour of British surgery never could have sprung into being. Familiar himself with all anatomical and physiological science, which he had acquired by long and arduous study, Dr. William Hunter poured the vivifying flood of his matured knowledge into the mind of his brother, John Hunter, and thereby enabled him to become all that he afterwards became. Verily, William Hunter cast a lump of shapeless clay upon the wheel, and moulded it into a form that is imagined by mankind, in their admiration, as even a thousand times more beautiful than it was in fact: the Physiologist and Surgeon, John Hunter, was the unquestionable handiwork of the Physician and Anatomist—William Hunter. At the present day, if the business of teaching anatomy in London be mostly in the hands of surgeons, there are still two of the leading schools where that important duty is performed by physicians—University College, and King’s College.

As to Mr. Earle’s speaking of any theoretical view of Dr. Copland, as “a subtle poison extending over all the

doctrines contained in the Dictionary of Practical Medicine,” the allegation will be treated as it deserves, by all who know aught of the matter. Who ever reared a more honorable monument to his science, his practical acquaintance with disease, and his industry, than James Copland has raised to himself in his Dictionary? A learned physiologist he, and I stake my credit, from personal knowledge of the man, at least as good an anatomist as Mr. Earle.

Your obedient servant

A PHYSICIAN AND AN ANATOMIST.

London, April 12, 1844.

ANALYSES AND NOTICES OF BOOKS.

“L’Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D’ALEMBERT.

Scrofula; its Nature, Causes, and Treatment; and on the Prevention and Eradication of the Strumous Diathesis. By W. TYLER SMITH, M.B. 8vo. pp. 172. Churchill.

As our commercial speculators are on the watch to act upon an ill-supplied market, and at the favourable moment to throw in a cargo or so of the article wanted, so our literary *entrepreneurs*—we are forced to go to the French for a polite word—are wont to look down upon their market, and seeing a gap, as they conceive, to essay forthwith to stop it. The book before us has intrinsic marks of the *stop-gap* about it. We have been long without any work on scrofula, of the least likelihood, in English; but it is not by an essay, written with however fluent a pen—and the pen that wrote this essay is fluent—from a very limited circle of personal observation, and without the slightest pains to gather materials from abroad, that the deficiency is to be supplied. In the whole range of disease, there is none into the causes and essential nature of which we are more interested in inquiring than into those of scrofula. Dr. Smith’s book does not dispel one shade of the deep darkness in which we are involved in regard to such information; it is not even a little candle seen amid the gloom. We have not actually made up our minds as to what is and what is not scrofula, and Dr. Smith does in no way help us to do so. Surely he who undertakes to write ought to have it for his object to instruct. But the same sources of information that were

CICERO.

THE GRINDING SYSTEM.

THE

TRUE RADICAL REFORM THAT IS REQUIRED.

THAT "use makes perfect" is acknowledged on all hands to be true; and there is, perhaps, no art or science, among the many that are exercised in this great metropolis, which has arrived at higher perfection, than that which has CRAMMING the young men who are about to present themselves for examination at Surgeons' College, and Apothecaries' Hall, for its object. There is one gentleman in particular who excels in this art, who knows to a nicety when each of the subjects who commit themselves to his care is in a state fit for presentation at Bridge Street, Blackfriars, or Lincoln's Inn Fields—just as the feeders of the geese at Strasburgh know to a tittle when each animal's liver is in the proper state to be made an element in the celebrated "*Paté de foie gras*." This gentleman, a man of naturally acute mind, of liberal education, of the most untiring industry, and wonderful physical capabilities—a perfect cyclopædia of the medical and accessory sciences—has studied the art of CRAMMING for the Hall and College so long, and so closely, that there is probably no single question that was ever asked at either of these dreaded institutions which he has not down, black upon white. It is impossible to take him aback; he even knows the proper answer for each examiner; for the answers differ in different cases:—"If A asks you so and so, you will answer thus; but if B asks you the same question, you will answer differently, thus." The respectable

Society of Apothecaries were surprised and delighted during a portion of one season with the wonderful and accurate knowledge which the young candidates for their license displayed, without any distinction, of the classes, orders, genera, and species, of the specimens of rare plants submitted to their inspection. Many a professed botanist would have said, "I see it is a rosaceous plant, or a rosaceous plant, as the case might be, but I am not acquainted with the species." Our young gentlemen who, in the fields, would have been puzzled between a nettle and a dock, had the whole story put—natural order, according to Jussieu and DeCandolle: sexual position, according to Linnæus; class, genus, species, name, properties, and habit; nothing was wanting. The worthy Society were delighted: what botanists, what accomplished young men, were they sending forth under their auspices into the world? But, alas the day! the uniformity of the extent of botanical knowledge possessed begot suspicion, and it was by and by discovered that the specimens destined for the Hall paid toll of branch and blossom each, in its passage thither, and that the accomplished botanists were geese crammed upon the ipseissima specimina, and who, as aforesaid, could not have analyzed and assigned its place to the commonest weed of the fields.

This system of grinding, as now pursued, however, is a serious and a growing evil; there is, in fact, moral contamination in it, and means for its suppression ought to be concerted and enforced. Young men come up to London, mostly believing that they have a serious task before them, well disposed to make the best of the opportunities which their parents and friends, often at great sacrifice to themselves, afford them of acquiring a knowledge of the profession which is to furnish

them with bread, and to give them their standing in society. But they too commonly soon discover that there is another, and an easier, and a shorter way of getting up the information which is to enable them to pass the Hall, and, alas! as they often ignorantly think, that is to give them the knowledge which is also necessary to commence the practice of their profession withal. It is only when it is too late to recal misspent time that they find out their error, and begin to curse their folly; it is when they discover themselves condemned to hopeless drudgery in the lowest ranks of the profession, and excluded from the society of all that is respectable above them, that they bitterly, but vainly, regret the days, and months, and years, spent in folly and dissipation, which ought to have been given to mental culture, to preparation for the responsible duties of the medical practitioner.

How shall the evil be assailed; where lie its roots, that they may be struck at? In ignorance mainly; in self-interest; in the want of an efficient police of our medical schools; and also, in some considerable degree, in the constitution of the examining bodies of the Apothecaries' Company, and Surgeons' College.

There is at this moment a kind of moral disorganization prevalent in most of the medical schools of London, which calls far more loudly for reform than many things which occupy a larger share of the general professional attention. At some of these schools the classes are deserted; where there ought to be from sixty to seventy listeners, there will be seen three or four, eight or ten: one lecturer last summer began his Course, to which he had at the time between thirty and forty entries, with a single auditor; at his second lecture he had none!

And yet every young man who pays his fee to these lectures, knows that at the end of the session he will have his

schedule—filled up as to attendance by himself—duly signed by the lecturer. He who should refuse would have no one to enter to him: if A. be so scrupulous as to require attendance before he signs, the thing is soon known; and as B. will put his name to the indispensable certificate without any such condition, of course B. is preferred to A.;—the knave soon drives the honest man from the field.

The College of Surgeons' and Apothecaries' Company, if they require attendance, ought to take the responsibility of enforcing it out of the hands of the lecturers; the lecturers cannot compel attendance. These societies are not so poor but that they could pay a certain number of respectable officers, say two or three each, whose duty it would be to visit every class-room in London, and, furnished with a list of the enrolled, to ascertain, by calling over the names, that they were present. The periodical registrations at the Hall and College are absurd and nugatory, and altogether incompetent to meet the evil. Fares by the second and third class railway carriages are not so high as to make the trip to London at each of the trimestral periods a matter of great consideration. And then, what signifies the young man's incessant presence in town, if his mornings be passed in bed, his noons in loitering about the streets, and his nights at the theatre, the smoking divan, or some such elegant place of entertainment as the Cyder Cellar, the Coal Hole, or the Garrick's Head? He had a thousand times better be in the country, engaged in the occupation useful to another at least, if not to himself save as a means of present existence, of compounding and preparing medicines. He would still say to himself: "I live meantime, and what signifies attendance at the lectures on chemistry, and materia medica, and anatomy and physiology, and surgery and medicine, botany, midwifery,

legal medicine, and all such stuff, when for five pounds, Power, or Steggall, or some other apt hand, will give me as much in three months of these various branches of difficult lore as they know at the Hall and the College, and as will carry me through either of them triumphantly? And what if I *am* plucked? The Grinder has engaged to see me through for the money paid, and he must just take me in hand for six weeks or three months more." The disgrace of rejection is thus readily shifted from their own cowardly shoulders to the broad back of Mr. Power or Dr. Steggall: it is the business of these gentlemen to get the student through, rather than his own; if they fail, the discredit attaches to them rather than to him. And in this light is this thing actually viewed. It is not said, "Mr. so and so was plucked last night, and Messrs. so and so passed;" but it is, "one of Power's men or one of Steggall's men was plucked last night, and seven or more of Power's or Steggall's men passed!" There is quite an *esprit de corps* in the whole affair, in which both the student and the public are left entirely out of the question. Each triumph is a victory of the grinder over the corporate bodies; they are beaten, they are *done*; each defeat is the grinder's disgrace, not the idle student's. Nor is rejection to be viewed as any the slightest security to the public against intruders into the sanctuary of *Æsculapius*. No, it is only that the grinder had not achieved his work well in the particular instance, that the Hall or the College was not beaten, was not *done*, for the moment; it will certainly be so before three months have elapsed.

As for the information that is obtained by this system of cramming, it is a vapour, a shadow, more flimsy and fleeting than the morning mist before the sun. It is all imbibed in three months; in three months more it is all

gone; of principles, foundations, there were none. It is an extemporaneous, pasteboard castle, built upon sand. It is the momentary agitation of the stagnant pool by a stone cast into its middle—there is a ripple and a stir for an instant, and then all is smooth and motionless and unimpressed as before. Oh, it is a vicious and an unworthy system, such as no well-informed, high-principled young man would be a party to; it is a cheat and a lie, both to himself and the world. The ignorant young man thinks he is dieting upon solid food; and by and by he finds that it was ashes, and a dream with which he was banquetted.

Whence the idea so strongly impressed upon the medical student's mind, of the necessity of subjecting himself to this degrading, this deceitful system of grinding? It exists more especially with reference to the Hall,—young men rarely grind for the College; and the very soul of the evil we believe to be this: the extent and multifarious nature of the subjects insisted on at the *one* examination at Apothecaries' Hall, and the construction of its Court of Examiners—men all past the meridian of life, and, with few exceptions, themselves of limited education and acquirements. These men's ideas turn perpetually round within a very narrow circle, and one and all they have certain crotchets, right or wrong, which they must have indulged; unless they have the special answer to the special question, they reject the candidate. We have been informed of a young man who carried off the gold medal at Mr. Daniell's class against all competitors, competent in the laboratory with his tools about him, to undertake the most difficult analysis, brimful of all the science of modern chemistry, rejected upon a simple chemical question, by an elderly gentleman at Apothecaries' Hall! Nor is this any single instance—the

like occurs every now and then; young men who have been noted for their regularity in the anatomical theatre, and their diligence in the dissecting room, who have borne away the anatomical prize in face of their fellows, have been plucked upon an anatomical question in the same evening that lurdanes, whose faces were never familiar at any theatre, save Astley's, the Surrey, or the Strand, have passed triumphantly, and added another to the many wreaths—of withered leaves—that already crown Mr. Power's and Dr. Steggall's brows. These Courts of Examiners, both at the College and Hall, want new, young blood infused into them; and no individual examiner should have the right of rejection in himself. Where there is a doubt, a majority of the court should forthwith be constituted a Committee for testing fitness, and the decision of this, and this alone, be allowed to be final.

But we have gone far beyond our usual limits in these remarks, hurried away by the all-importance of the subject. It will afford us theme for further commentary.

ROYAL MEDICAL & CHIRURGICAL SOCIETY.

Tuesday, April 9, 1844.

THE PRESIDENT IN THE CHAIR.

On the Oxalic Acid Diathesis. By H. BENCKE JONES, M.A. &c.

THE author commences his paper with a quotation from M. Vigla, who, in 1838, says, "Nous avons fréquemment observé dans les sédiments ou les cremors de l'urine de semblables cristaux (octaédriques) que leur forme aurait pu faire supposer être formés de chlorure de sodium, si la solubilité de ce sel, et la petite quantité qui s'en trouve dans l'urine, avaient permis de s'arrêter à cette idée."

Dr. Golding Bird, in 1842, stated that these octohedral crystals were oxalate of lime. No chemical proof having (as far as the author knows) been given, he was led to analyse the sediment. On examining urine for this purpose, the very frequent occurrence of these crystals in rheumatism was observed. In one case, in which the rheumatism was slight, the influence of diet and exercise on

the mixed deposit of urate of ammonia and oxalate of lime was made the subject of experiment.

In other cases in which the crystals occurred, the symptoms were altogether different, irritation of the urinary organs being the most prominent. The concretion of the crystals into oxalate of lime gravel seemed (in one case at least) to be the cause of this diversity of symptoms.

The author observes that these crystals do not often occur in sufficient quantity to admit of analysis, but in Oct. 1843, he examined the urine of a patient of Mr. Cutler's, and at the same time three small renal calculi, which had been passed in July, August, and September. The urine under the microscope contained multitudes of octohedral mixed with some crystals of uric acid. All the calculi consisted of oxalate of lime mixed with uric acid.

The author has also examined cases of acute rheumatism, and always found the presence of these octohedral crystals in the urine of patients labouring under this disease. This deposit is also not unusually found mixed with urate of ammonia in chronic rheumatism. In one case he was enabled to make some experiments on the effects of diet and exercise on the deposit of urate of ammonia, and in it he observed that the octohedral crystals varied in quantity at different hours of the day. The daily results of this experiment are given very minutely, during the four weeks it lasted.

The author states it would be easy to multiply examples of the connection between octohedral crystals and rheumatism, but as it indicates no variation in the treatment of the disease, the fact seems only interesting as shewing the close connection between the red deposit and octohedral crystals, and thus giving additional support to the theory of Professor Liebig regarding the origin of oxalate of lime.

The presence of octohedral crystals in the urine is frequently accompanied with symptoms of a totally different kind. The patient complains of pain in the loins, frequent desire to pass urine—which is sometimes small in quantity, at other times so large as to simulate diabetes. There are sudden calls to empty the bladder, and if they are delayed considerable pain is produced. The urine when examined contains only a slight cloud, which does not disappear on the application of heat. When examined by the microscope, this cloud is seen to consist sometimes entirely of octohedral crystals; more frequently of these crystals mixed with globules of mucus, and sometimes there are large and small scales of epithelium.

The symptoms closely resemble those produced by a small calculus in the kidney; and in one case they suddenly ceased after

sharp pain in the course of the right ureter, and slight retraction of the testicle.

The author concludes by observing that the treatment which has proved most beneficial has been that which improved the general health. In two of Mr. Cutler's cases the symptoms appeared to follow mental anxiety. Medicines had little effect, but as the cause for anxiety disappeared, the symptoms ceased.

Case of Aneurism of the External Iliac, in which a Ligature was applied to the Common Iliac Artery. By RICHARD HEY, Esq., F.R.C.S., Surgeon to the York County Hospital.

THE patient, a gentleman aged 40, perceived, 10th November, a small hard tumor in his left groin, above the centre of Poupart's ligament. Three days afterwards he had severe pain in the part, and on the following day the swelling increased in size, accompanied with pulsation. The tumor gradually enlarged, assumed at one part a conical shape, and the skin was tense and red. By moderate continued pressure the swelling could be reduced in size; but it resumed its former magnitude when the pressure was taken off. It was resolved, in consultation, to apply a ligature to the common iliac artery, which operation was performed by the author on December 3. At this time the tumor measured six inches across, in a transverse direction; six and a half longitudinally; and projected three inches from the plane of the abdomen. At one point it was about an inch and a half from the navel. The incision was begun $2\frac{1}{2}$ inches above the navel, and 3 inches from the median line, and was carried six inches downwards, in a semicircular direction, with a prolongation of an inch and a half in a straight line outwards. The layers of muscles and fascia transversalis having been divided to the whole extent of the incision, the peritoneum was gently separated from the parts beneath, and the common iliac artery was easily reached. A little time was occupied in scratching through the sheath with the point of the aneurism needle; after which it was passed under the artery, from within outwards, armed with a double ligature of stay-maker's silk, and the operation completed. The pulsation in the tumor ceased immediately after the artery was tied. The patient proceeded on the whole favourably after the operation, except that he was in great danger at one time from an accumulation of hardened feces in the rectum. The tumor gradually subsided in size; and both legs were nearly of the same temperature, the affected limb being kept surrounded with flannel. A week after the operation pulsation was felt in the anterior tibial artery. On the 28th day the ligature was found

loose in the wound, and removed. About the 20th of January the patient was free from complaint, and was able to walk about.

Mr. Hey, of Leeds (*see deficit alter.*), entered into a few particulars in addition to those given in his paper. The limb, after the operation, was merely involved in the finest, softest flannel; no other measures to maintain the temperature at a point which was held compatible with its life were found requisite. He spoke of the advantages of the incision which he had adopted over that which has usually been chosen, and stated that he believed he should have felt little or no greater difficulty in putting a ligature around the aorta above its bifurcation, than he did in securing the common iliac: indeed there was no difficulty experienced in doing this; the only pause in the procedure was owing to the aneurism needle with which he attempted to open the sheath of the vessel having been too much bent; Mr. Teale took it from his hand, straightened it, and immediately afterwards he had the artery disengaged. He adverted to the rapidity with which the aneurism had increased, and the great risk that was incurred by even the few days' delay which the hesitation of the patient to submit to a formidable operation had occasioned. In three weeks, it had grown from the size of a hazel-nut to a tumor which must have been as large as the largest shaddock. There were even apprehensions entertained that it might burst in the course of the manipulations inseparable from the operation. The sinus formed by the ligature did not heal, and the discharge from it having suddenly increased greatly, it was found that the aneurismal sac, in its greatly reduced state, had suppurated. The only unpleasant symptom from which the patient suffered during his convalescence was severe spasm of the rectum, tenesmus, and a sense of weight and bearing down, which it was apprehended at one time would make the remainder of the patient's life miserable. By and by, however, it was fortunately discovered that the whole of the patient's misery in this direction was occasioned by the presence of a large mass of indurated feces within the bowel. This being broken down mechanically, and removed, the patient was immediately relieved, and then went on satisfactorily.

The President inquired whether the patient complained of any weakness in the limb afterwards?

Mr. Hey replied that he did, but only occasionally, complain of slight weakness in the ankle.

Sir G. Lefevre adverted to a successful case of ligature of the common iliac, performed by Dr. Solomon, of St. Petersburg, the particulars of which Sir George had himself transmitted to this country. He

was pleased to learn that his account had been published in the *MEDICAL GAZETTE*.

On a question as to the issue of the operation of tying the common iliac, the President enumerated several instances in which it had been done; and Mr. Paget referred to the first volume of the *LONDON MEDICAL GAZETTE* for the Session 1842-43, for an account of all the cases on record.

On Obstructions of the Pulmonary Arteries.

By JAMES PAGET.

THE obstructions treated of are those produced by clots of blood formed during life. They occur in nearly all cases in which the capillary circulation through a part of a lung is prevented for a considerable time before death: and this, in consequence of the arrangement of the pulmonary arteries, which do not anastomose, except at their smallest branches and in the capillary system; so that whenever any part of that system is obstructed there must be a stagnation of the blood in all the branches of the arteries leading to that part. Branches of the pulmonary arteries are usually found filled by old coagula, in cases—1st, of compact pulmonary apoplexy; 2nd, of extreme oedema of the lungs, especially in that form which is attended by peculiar rottenness of their texture, and which is apt to supervene in old persons upon disease of the heart, or emphysema after repeated attacks of bronchitis; 3d, of pneumonia with solid deposit; 4th, of cancer of the lung, when cancerous matter has been conveyed by the circulation into the branches of the pulmonary artery. Cases of the occurrence of such coagula in these several diseases are related.

But besides these cases, in which the formation of the coagula is in a greater or less degree the consequence of obstruction of the capillaries of the lung, there are others in which it appears as the chief and primary disease.

Three such cases are detailed. In all of them numerous branches of the pulmonary arteries of the second, third, and more distant orders, were completely blocked up by coagula, which had evidently been formed long before death, and besides which no sufficient cause of death could be found. In one of the cases some of the coagula had become organized, and formed pale, firm, bands and loops attached to the walls of the artery. In two of these cases there was no indication whatever of inflammation of the pulmonary artery, or its branches, having existed: they were in all respects healthy, except in having spots of yellow deposit in their coats, a change which the author states to be very common in the secondary and smaller branches of the pulmonary artery. In the last case related, there were abundant

fibrinous deposits in the pulmonary valves, with wart-like growths, and ulceration of the adjacent part of the artery. There were only two valves in this pulmonary artery, and the author takes this occasion to mention the fact, that in the majority of cases in which only two valves have been found in the pulmonary artery or aorta, those valves have been diseased. He points it out as an example of a congenital defect in the shape of a part being accompanied by a more important congenital imperfection of its tissue; and alludes to the necessity of considering the latter imperfections as predisposing causes of disease in the imperfect part.

Mr. Hewitt mentioned several cases in which he had lately met with but two semilunar valves at the roots of the great arteries. In two cases there was disease—vegetation—of the valves; in a third the valves were healthy, and performed their office perfectly.

Mr. Paget observed, that in cases of valvular malformation there was greater liability to disease than usual; but he held that this was more owing to imperfection of tissue or texture, than to alteration of shape.

ELECTIVE POWERS OF
THE LACTEAL VESSELS.

WHILST some are of opinion that the lacteals absorb indifferently all the substances they encounter in the intestines; others, and particularly M. Magendie and his school, maintain that the veins alone take up articles that are poisonous to the economy. Some late experiments of Chatin confirm the latter view. Eight dogs having each had 0.50 gram. of arsenious acid mixed with milk introduced into their stomachs, the animals were by and by bled to death. The blood of the whole incinerated with nitrate of potash and put into Marsh's apparatus, a ring and stains of arsenic were obtained. The chyle, obtained by dividing the thoracic ducts of the eight animals, treated in the same way, did not afford a trace of the metal.

A similar experiment, merely substituting tartrate of potash and antimony for arsenic, was performed, with the same results; the antimony was detected abundantly in the blood, the chyle was without a trace of it.—*Comptes Rendus*, No. 10, 1844.

KERATOPLASTIC: TRANSPLANTATION OF
THE TRANSPARENT CORNEA.

M. FELDMANN, of Munich, has sent two memoirs on this subject, to the Royal Academy of Sciences of Paris. The experiments quoted in the second paper do not appear to have been very successful. The transplanted cornea could generally be got to adhere indeed, but then it shrank to half its original size and became *perfectly opaque*, so that nothing was gained.—*Ibid*.

STATISTICS OF INSANITY

In the Duchy of Brunswick, by Dr. Mansfeld.

THE interval embraced in this report extends from October 1841, to March 1842.

The whole number of patients is 488, of whom 254 are males, 234 females.

Of the 488, 17 are from 5 to 10 years of age; 61 from 10—20; 103 from 20—30; 99 from 30—40; 86 from 40—50; 74 from 50—60; 37 from 60—70; 8 from 70—80; and 1 between 80 and 90.

Of the whole number, 64 are married; 394 single; 27 widowed; and 3 separated.

The number of poor patients is 383; of those possessed of means, 105.

The form of the disease is furious mania in 25; delusion in 72; melancholy in 38; and amentia, or idiocy, in 358.

Of those affected with mania, 11 have suffered for five years, 14 for a longer time; with dementia, 26 for five years, 46 for a longer time; with melancholy, 16 for five years, 22 for a longer time; and with amentia or idiocy, 75 for five years, 278 for a longer time; and of the entire number, 216 have been idiots from birth.

Among the insane patients, 25 men and 29 women, in all 54, are subject to epilepsy.

The ratio of the insane to the entire population is as 1 : 539.—*Oppenheim's Zeitschrift*, Jan. 1844.

CONTRACTION OF THE
FORAMEN LACERUM POSTERIUS,
IN MANIACS AND SUICIDES.

THE professor of anatomy in the University of Kiew, Dr. Kasloff, has for several years directed his attention to the state of the great vessels of the brain in cases of insanity, and finds himself forced upon the conclusion, that insanity in all its forms is most intimately connected with derangement of the circulation within the cranium. In the course of the year 1841, he had particular occasion to remark, that the foramen lacerum posterius was very commonly contracted in the skulls of those who had died insane, or who had committed suicide. The contraction generally occurred on one side only, rarely on both. In many cases he found the foramen, where it transmits the internal jugular vein, reduced to a mere narrow slit, which with difficulty admitted a common probe. The furrow for the lateral sinus, which led to this contracted foramen lacerum, was neither so broad nor so deep as in ordinary skulls, and the thimble-like cavity was almost level with the base of the cranium. The jugular vein that occupied it could not have had half, frequently not one-third, and occasionally not one-fourth of its usual diameter. The canalis caroticus of the corresponding side did not appear to have undergone any similar contraction of its diameter. Along with the contraction of the foramen lacerum posterius, however, a conspicuous enlargement of those foramina which transmit veins from the interior to the exterior of the skull was very regularly observed: the foramen mastoideum, and foramen parietale of the corresponding side, for example, were found of two Paris lines in diameter, and supernumerary foramina presented themselves in situations where none are commonly seen.

In every skull of a maniac or suicide in the anatomical collection at Kiew, Professor Kasloff observed the contraction of the foramen lacerum posterius in a greater or less degree upon one or both sides; in seventeen of the twenty-one skulls belonging to the above category, the peculiarity was remarkably displayed. On comparing the foramina lacera of the two sides, he found that where the one on the healthy side was four and a half Parisian lines in diameter, the contracted opening measured but two lines; where the healthy orifice measured four and a quarter lines, the contracted one still measured only two lines; where the former measured three and a half, and two and a half lines, the latter measured but one, and one and a half line.

In quoting these facts, Professor Kasloff still admits that he has examined other skulls of maniacs where he observed nothing of the same kind. It is impossible, however, not to regard the instances quoted as full of interest for the pathology of insanity. At

seems quite certain that the afflux through the carotid and basilar arteries continuing unimpeded, if any, even a very slight hindrance to the return of the blood by one of its principal channels be encountered, a stasis or accumulation within the vessels of the brain must of necessity ensue, and that this can be without influence upon that important organ, "the soul's frail dwelling place," is admitted on all hands to be impossible. Now, here is a permanent obstacle to the due return of the blood from the brain, which if it have not entirely escaped the notice of pathological anatomists, which it has not, appears never to have been viewed till now in its legitimate connection with and bearing upon functional derangement or organic disease of the brain.—*Zeitsch. f. d. gesammte Medicin, von F. W. Oppenheim, January, 1844.*

INDISCRIMINATING HUMANITY OF MEDICAL MEN.

DR. ANTHONY PETIT, reproached upon a certain occasion by the Queen, Marie Antoinette, for not appearing at Versailles as had been expected, replied—"Madam, if I came not to Versailles yesterday, it was because I was detained with a peasant's wife in her confinement, and in imminent danger of losing her life. Your Majesty errs, moreover, in supposing that I neglect the Dauphin for the poor; I have hitherto treated the child with greater care and attention than if he had been the son of one of your Majesty's grooms."—*M. Arago, Eloge de Bailly.*

LARREY.

PREFERENCE of the greatest sufferer, without regard to rank or station—such has ever been the sublime rule of the body medical, and such is still its evangile. To his personal friend Tanchou, wounded at the battle of Montmirail, Larrey said—"Your wound, my friend, is slight: we have room and straw in this ambulance for the severely wounded only; you will be lodged in yonder stable."—*M. Arago, in his Eloge de Bailly.*

BARON HUMBOLDT.

THE house and garden which this distinguished man occupies at Berlin was some time back sold to a merchant, who forthwith gave notice to his tenant to quit. The banker, Joseph Mendelssohn, having heard of the circumstance, immediately set on foot a negotiation for the repurchase of the property, which he effected at a very high price. He forthwith sent his respects to M. de Humboldt; assured him he should not be disturbed in his old habits and associations, and that the house and garden were at his disposal so long as he chose to occupy them.—We kiss thy hands with all our heart, kind Joseph Mendelssohn! May thy dollars multiply, since thou hast the soul to use them so!

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

List of Gentlemen admitted Members, April 12.—J. C. Barker.—B. Eddison.—R. Roe.—A. C. Morse.—A. P. Schuyler.—E. C. Hulme.—T. Oldacres.—H. Fenton.—J. H. Bennett.—R. Hassall.—T. Massey.

SECOND CLINICAL
LECTURE ON TETANUS,

Delivered at St. Thomas's Hospital,

By SAMUEL SOLLY, F.R.S.

Senior Assistant Surgeon and Lecturer on Clinical
Surgery at St. Thomas's Hospital.

(For the London Medical Gazette.)

GENTLEMEN,—When I last addressed you I little thought how soon I should have occasion again to call your attention to the pathology and treatment of tetanus. But two cases of the disease having been admitted within the last fortnight, I must not lose the opportunity of recurring to this interesting subject; to which, indeed, I am the more disposed, as the result, fortunate in our first case, has been disastrous in the two last.

George James Howes, æt. 28, undertaker. States that about eighteen months ago he struck his right leg with a spade and grazed the skin upon the lower part of the shin; he took no notice of the accident, and the sore has continued to get larger and larger till Monday, March 11th, when he was seized suddenly with a stiffness all over his body, so that he could not get out of bed: he had got very wet the day before, and had kept his wet clothes on. A medical man was sent for, who ordered him some medicine, and on the Wednesday his leg was examined, and found to be in a very bad state, and exceedingly offensive. He continued to get worse, and being sent to St. Thomas's Hospital he was there admitted under Mr. Green on the 19th of March.

The patient now complains of a pain in his loins, which extends up the spine, and about every half hour catches him suddenly, and draws him stiff and backwards. When the pain comes on, his jaws are also forcibly brought together; when free from pain he is not able to open his jaws more than a quarter of an

856.—XXXIV.

inch; he also feels a stiffness about his chest, which, he says, prevents him from coughing or sneezing, and causes him to draw his breath short and sharp. His paroxysms come on if he is spoken to suddenly. His head feels very heavy; he cannot show his tongue; pulse 133, and sharp; bowels have not been opened since Sunday, when they were relieved pretty freely and frequently, with much flatus passed per anum. Ordered by Mr. Solly—

Calomelanos, gr. v. statim, et rep. 4ta horâ nisi priusquam responderit; Vin. Rub. ʒvj. Eggs, arrow root. Emp. Lyttæ Spinz Enema Tabaci, (ʒj. ad Oj. Aq.) pars dimidia quamprimum infundenda.

The sore on his leg is a large superficial ulcer extending from the inner side over the front of the leg.

Cataplasma. Lini Ulceri.

4 P.M.—The enema had only now been administered; he has had one dose of the calomel, and his bowels have not acted. Pulse 120, pretty full.

6 P.M.—The injection seems to have had very little effect on his pulse; the other half is therefore to be thrown up: he swallows better than he did, but his breathing is still very difficult. The enema came away almost immediately.

Half-past 9 P.M.—Mr. Solly saw him again; bowels have acted, but not copiously. Pulse 130, jerking; he perspires profusely; paroxysms not so frequent, but the breathing is not relieved.

Half-past 10.—Injection repeated, immediately after which he had a motion, which seemed, however, to consist entirely of the enema. Ordered—

Brandy, ʒvj.; Beef-tea, Morphine Acet. gr. j. ad opus sit.

He takes his wine pretty well, but sometimes he has great difficulty in swallowing.

20th, 9 A.M.—He has dozed a good deal

B

during the night, and his bowels have been freely opened; the blister down the spine has risen well. His breathing is very much oppressed, and there is evidently very great obstruction in the bronchial tubes; when he makes the attempt he gurgles all out again; his countenance is livid; his spasms much less frequent; his pulse 120, but much weaker. Ordered—

Cal. gr. ij. 2dis horis; Træ. Cannabis Indicæ, ℥xx. 3tis horis sumend. If he cannot swallow, to double the quantity to be given as an enema. A blister to be raised on the chest by hot water as quickly as possible, and the cuticle being removed to dress it with Ung. Hydrarg.

1 P.M.—Much weaker; countenance much more livid; cannot swallow without great difficulty; pulse much more feeble. He continued from this time to sink gradually, and died at 3 h. 40 m. P.M.

In this case the tetanus could not very clearly be attributed to the wound, which had existed for eighteen months, and at the time of the patient's admission was simply an extensive indolent ulcer. I inquired particularly of his companions whether he had received any fresh injury on his leg, or whether the sore had lately assumed any different appearance, but I could not learn that it had. The immediate exciting cause appears to have been exposure to wet and cold, from getting his clothes soaked, and allowing them to dry on his back. Damp cold is well known to be one of the most frequent causes of idiopathic tetanus, under which head, I think, *Howes'* case must be ranked: we should hardly be justified in regarding it a case of traumatic tetanus.

The course of the disease was rapid for the idiopathic form. The patient was first seized on the 11th; on the 19th he was admitted into the hospital. He died on the following day. This case was complicated by chronic bronchitis, which certainly accelerated the fatal result.

We of course all regret, gentlemen, that the friends removed the body without granting us the opportunity of making a post-mortem examination.

With regard to the treatment, you will perceive that I pursued the same plan which had apparently answered in the last case I brought under your notice. The calomel and the tobacco enema were given with the view of emptying the bowels. I thought it right to give the Indian hemp another trial, at the same time not allowing the administration of it to interfere with what I considered the more essential part of the treatment. The bronchial affection went on so rapidly, that it was very evident, unless it could be arrested at once, it must very shortly prove

fatal. In such cases, and under such circumstances, you will find the plan adopted, namely, that of raising a blister on the surface of the chest, by means of hot water, and then dressing the denuded surface with mercurial ointment, one of the most efficient local antiphlogistic measures you can have recourse to. But all our remedies were in vain.

Tetanus is certainly a very rare disease in these countries, but, singularly enough, not many days elapsed before we had another opportunity of testing the value both of general and local means in the local antiphlogistic treatment of this alarming affection; and here, as in the case just commented on, we had our hopes deceived, and our pride humbled, by their utter failure. But to you, gentlemen, as to us, unsuccessful cases are frequently even more instructive than successful ones, if we only analyse and examine them candidly.

Four days after the death of poor *Howes*, we admitted a lad of the name of *James Godden*, æt. 13. He is of spare habit, and good complexion. He states that on March 12th he fell from an elder tree, and lighted on a hedge, and that a piece of wood struck him and wounded him behind the left ear: two or three days after this his father noticed his features to be somewhat distorted, which he thought was owing to some bad tricks he had got, and chided him for it: the distortion, however, increased, and the boy was brought to the surgery at *St. Thomas's Hospital* on the 23d of March.

The features are now drawn over to the right side. On examining the part that had been injured, there was found an ill-conditioned sore on the left mastoid process, and a degree of puffiness about it; a free incision was made into the part, and on examining with the finger, two pieces of wood were found in the wound, and removed. A poultice applied over the part, and the boy was taken home.

March 24th.—He was brought to the hospital to-day; he looked very pale; has since this morning been unable to open the mouth more than half an inch; the sterno-mastoids are very rigid, and also the muscles at the back of the neck; the features are much more drawn to the right side; he can swallow very well; pulse natural; wound painful, but not inflamed. Ordered by Mr. Solly—

Cal. gr. iij. 6ta horis bis Enema Terebinth. amplum statim adhibend. The wound to be dilated towards the ear, and thirty leeches to be applied around it.

4 P.M.—Is much easier, and more cheerful; has had a copious motiop.

8 P.M.—Mr. Solly saw him again: eyes more closed; sterno-mastoids much relaxed; but seems to have a good deal of spasm about the muscles of the back; pulse 88.

25th.—Has dozed a good deal during the night; his bowels have been freely opened two or three times; his features are rather more distorted; he has complained of twitching pains in his legs; mouth more firmly closed—he can scarcely get the tip of the finger into the mouth. Some rigidity of the posterior cervical muscles; pulse less powerful. Ordered—

Arrow Root, Wine, $\mathfrak{z}\text{iv}$.; Brandy, $\mathfrak{z}\text{ij}$.; Tinct. Cannabis Ind. $\mathfrak{m}\mathfrak{x}\mathfrak{x}$. 4tā quaque horā sumend. Emp. Lyttæ Spinæ.

4 P.M.—Mr. Solly saw him again: he has had some spasmodic twitches in the back to-day, which have given him a good deal of uneasiness. The Tinct. Cannabis Ind. seems to excite spasm in the throat: it was therefore ordered to be administered in double quantity per anum, and if this dose does not excite any spasm, to have $\mathfrak{m}\mathfrak{x}$. 3tis horis. His spasms continue recurring every quarter of an hour; he seems to have no disposition to sleep; the bowels have not been open, and he has not passed water since the morning. A catheter was therefore introduced, and a large quantity of water was drawn off. He complains of great irritation from the blister, which was therefore removed: it had risen well, and was then dressed with a poultice.

Is to have the Enema Cannabis twice repeated.

20th, 10 A.M.—Has passed a restless night, the spasms recurring as frequently as ever: his jaw is locked firmly: the spasms draw his head back, and affect his back strongly; his abdominal muscles are tense and hard, whilst they last; his bowels have not been opened; pulse quick, frequent, 100. Ordered—

Enema Tabaci, $\mathfrak{z}\text{j}$. ad lbj. dimid stat. adhibend.

2 P.M.—Had the tobacco enema at about twenty minutes to eleven, which returned in four minutes, but produced great prostration, and a profuse perspiration: in about half an hour he had a slight convulsive fit: at half-past one, as his bowels were not relieved, he had a common enema, which he retained. Bowels not opened. Ordered—Calomelanos, gr. ijj . stat.

5 P.M.—Mr. Solly saw him: he has had frequent calls to stool, but no evacuation; very restless.

\mathfrak{B} . Morphine, gr. ss. rep. 4tā horā somno absente.

Half-past 9 P.M.—Has been rather easier; paroxysms less frequent; seems inclined to sleep; has had no evacuation from the bowels.

27th.—Has had a more comfortable night, but about 5 A.M. was seized with another convulsive fit, which the night nurse says,

“held him two or three minutes;” he opens his mouth much better this morning, but the paroxysms come on again in his back as severely as ever; his bowels have not been relieved; drew off about a pint of urine with a catheter; pulse 130, of much less power. Ordered—

Enema Terebinth., Pulv. Jalapæ Co. $\mathfrak{z}\text{j}$.

He perspires freely; can swallow easily, and takes his wine, brandy, &c. very well.

1 P.M.—The enema caused a small evacuation. The patient is getting gradually weaker; the spasms increase in strength; pulse 144, with less power.

Half-past 4 P.M.—He is much weaker; inclined to ramble now and then, but knows those about him; spasms are stronger and more frequent; bowels have not acted again.

To have Enema Commune.

Half-past 6 P.M.—He was seized with a violent paroxysm, more convulsive than tetanic, which held him for a considerable time: when he came out of it, he evidently knew those about him, but did not speak. Another paroxysm recurred at ten minutes past seven, immediately after which he died.

Post-mortem, 18 hours after death.

Weather warm for the time of year.

General appearance.—Body plump; venous system generally full. Body mottled. Abdomen greenish. Wound behind the ear presenting a foul unhealthy appearance.

I commenced the dissection by making an incision horizontally a little below the external ear, from before backwards, in the direction of the auricular branch of the facial nerve. This branch, when exposed, exhibited the bright white shining appearance of a perfectly healthy nerve. I traced it onwards towards the wound, in the immediate neighbourhood of which its natural appearance was lost in common with that of the other tissues, which were all of a reddish brown colour, from infiltration of blood, &c. &c. I could not detect the slightest appearance of inflammation in the nerve or its neurilema. The trunk of the facial nerve was also traced from its origin in the medulla oblongata through the stylo-mastoid canal, till it emerges on the face from behind the parotid gland: it exhibited no abnormal appearance.

The periosteum of the bone beneath the wound was ulcerated, and the bone bare to a very small extent. There was a small fissure in the bone, about the size of the extremity of the nail of the little finger, and the teeth of an inch in depth, such as might have been made by a blow from a sharp hard piece of wood.

Head.—The vessels of the dura mater were full of blood, and the whole membrane more vascular than usual, even in a lad of 14 years of age.

No inflammation of either arachnoid or pia mater was perceptible, but the vessels of the latter were very turgid.

The substance of the brain generally was very full of blood. The cortical substance was dark, but not inflamed. The motor tract healthy throughout. The medulla oblongata was perfectly healthy. Permission to examine the rest of the body was not obtained.

I cannot help regarding this case as highly instructive. During life, every circumstance attending the progress of the disease seemed to indicate the symptoms as dependent on an extension of inflammatory action from the seat of injury to the nervous centre. On the 12th of March, for instance, this boy receives a trifling, but ragged, wound on the side of the head, just behind the ear. His father states that he suffered scarcely anything at the time—that he did not even complain of pain. But two or three days afterwards his features are slightly distorted, and as this increases his father brings him to the hospital on the 23d; that is, eleven days after the injury was inflicted. A partial paralysis of the muscles supplied by the portio dura is now observed. The wound, which presented an unhealthy appearance, is very judiciously dilated by the dresser, Mr. Carr, who, by that means, discovered, and was enabled to remove, two small pieces of wood. Such are the early symptoms in this interesting case. Let us pass them in review, and first ask to what we are to attribute the paralysis of the face? The wound was not in a position to affect the trunk of the portio dura; it was behind the ear, not in front of it. You are doubtless well aware that division of the trunk of the portio dura is followed by paralysis of the muscles of one side of the face, and that a simple swelling of the parotid gland from inflammation consequent on cold will sometimes produce the symptoms by pressing injuriously on the nerve. The portio dura sends a branch, called the *auricular*, backwards behind the ear, in the direction of this wound; and to this branch did I look as the instrument of communication between the wound and the facial nerve. I concluded, I candidly confess, during the life of the boy, that this nerve had become inflamed in the wound, and that this inflammation extended along the course of the branch, had attacked the trunk of the nerve, producing paralysis of the whole of its filaments.

The tetanus which followed the paralysis I attribute to an extension of the inflammation along this same nerve to its origin in the medulla oblongata, and the excitement there, and in the centres of reflex function along the spinal cord, giving rise to that spasmodic action of the muscles which we call trismus and tetanus. Trismus, you well remember, was the first sign of the univer-

sal tetanic spasms which followed. The masticatory muscles are not supplied by the portio dura, but by the muscular portion of the 3rd division of the 5th, which has its origin from the motor tract of the medulla oblongata, very near to that of the portio dura. It was evident that there was a reflected irritation of the whole of the excitatory system of nerves, and this I thought capable of satisfactory explanation upon the principles I have mentioned. How entirely, however, does the post-mortem examination subvert the opinion that this reflected irritation resulted from an extension of the local inflammation! There was no appearance whatever of inflammatory implication of the portio dura, no redness of the neurilemma, or thickening of the nerve. Another theory of the course and causes of the symptoms crossed my mind during the progress of this case; it was this:—that the injury had given rise to inflammation of the bone, which had extended through the medium of the mastoid cells to the stylo-mastoid canal, and thus to the portio dura. But the absence of any severe pain or other affection of the ear gave no countenance to this idea; and the examination after death shewed that nothing of the kind existed. Again, I thought it not impossible that the injury of the bone had produced consecutive inflammation of the dura mater, and then of the medulla oblongata and spinal cord: but neither was this hypothesis borne out by the necropsy.

No, gentlemen; the cause of the whole of these disastrous symptoms is not revealed to us by the post-mortem examination; the evidence which that affords is purely negative; it shows us that the symptoms were not connected with inflammatory action either of nervous cords or nervous centres; it shews us that tetanus in its severest and most fatal form can exist independently of inflammation of the nerves or nervous centres. And though I still believe that the conductor of the irritation from the wounds to the nervous centres was the facial nerve, it is clear to me that inflammatory action was not the vehicle or cause of its conduction in this case, and that therefore it is not an essential element in the pathology of tetanus.

I was much vexed that I could not be permitted to examine the spinal cord throughout its whole length; though the absence of inflammation at the origin of those nerves which were first affected renders it very improbable that there was any inflammation of the rest of the medulla spinalis.

It would also have been satisfactory if we could have examined the condition of the heart and lungs, for there is every reason to believe that the immediate cause of death in such cases is suffocation from spasm of the glottis and of the muscles of respiration generally.

The treatment in this case was guided by the general features of the disease rather than by any feeling that we possess a medicine which exerts a specific influence over tetanus.

Special attention was paid to the immediate relief of the bowels, which the turpentine enema effected in the first instance. The character of the wound, and the pain in its neighbourhood, seemed to indicate local depletion, and the power of his pulse at that time justified its adoption. The Indian hemp certainly did not allay the spasms, but on the contrary, seemed to aggravate them. The morphia evidently relieved him. You will recollect that the report states he was easier after it, and that he had a better night. With regard to nourishment and stimulants, the order to the sister was to give him as much as he would take in small quantities frequently repeated : but he took very little.

ON THE
DECREASE OF DISEASE THROUGH
THE PROGRESS OF CIVILIZATION.

By C. F. H. MARX, M.D.

Professor of Pathology in the University of
Goettingen.

[Continued from p. 45.]

(*For the Medical Gazette.*)

Nor is it only as seeking to remedy corporeal and mental evils by every means at command that the present period is distinguished; measures are now systematically pursued in many lands which satisfy us that civilization will not be to blame if the germs of disease are suffered to go on engendering themselves anew and undisturbed in future years.

It were easy to point out the particular instances in which vast strides have been gradually made in this direction, but to do this would lead us too far from our subject, and would make it imperative on us to enter into a special analysis of the state of the human family, and its efforts at improvement and independence. It will be enough if I adduce a few of the more remarkable and influential of the many means brought into play by advancing civilization to diminish disease, in order to carry conviction to the reader's mind that the indubitable decrease of disease cannot be ascribed to the absence of accidental epidemical influences, or to any thing like periodical cycles, but that it must be attributed to the efforts of the human mind, crowned with a

large measure of success, as uninterrupted efforts ever are, to circumscribe the causes of disease, to remove these entirely, and to dispute every inch of the ground with causes inimical to length of days.

When we look at the earliest circumstances in the life of the individual, we find everything vouching for the fact that each new century, each step taken in the path pointed out by enlightened religion and ennobled humanity, is distinguished by an increasing attention to the physical wants of infancy, and a diminution of its mortality. The solicitude even begins before children see the light, and is active the moment they do so: the relations between nature and art, in the important process of parturition, are much better understood now than formerly; well-timed interference is constantly saving the threatened life both of child and mother. And then we are better informed as to the necessity of proper nursing: children are much less frequently sent to perish upon spoon meat than they used to be; and even in the cases where a nurse cannot be commanded, the system of feeding pursued is better adapted to the tender organs of the infant, and less destructive, than it was in former times.

Much is also now done to guard against the temptation to commit child-murder; and fewer infants fall victims to the ignorance of mothers. Deserted or orphan children are commonly sent into the country during the first years of life, instead of being congregated in Foundling Hospitals situated in the midst of great cities, in which the mortality was always very high.

In the education of children we have not merely regard now, as formerly, to the development of the mental qualities; we pay some attention to the bodily powers; and in the event of any predisposition to disease, we seek by fair and reasonable means to repress its growth, or to eradicate its seeds.

The dress of the community, whatever room for improvement still remains among the female portion of it especially, is more convenient now than it was once; and all those articles that interfered with the free play of the organs are falling every day into greater and greater discredit. Infants are no longer swathed or swaddled as they

used to be: since corsets have been made more roomy and pliant, much suffering has been spared to our women: when such villainous contrivances to distort the human form divine shall have been discarded entirely, much greater benefit will ensue. The feet of the wealthier classes of our females are no longer crippled by the high-heeled shoes which our grandmothers wore, which made necessary exercise painful or impossible, at the same time that by causing the lower vertebræ of the loins to encroach upon the pelvis, they rendered labour difficult, and sometimes even fatal*.

We no longer grease and powder the hair, as did our fathers, by which we gain in cleanliness, and therefore in strength; and whilst we are aware of the necessity of watching the first and often painful process of teething, we the indispensable instruments of mastication, by which we are enabled to have art to supply us in later life with maintain the stomach unoppressed, and the body effectively nourished, to the very end of our days, and so undoubtedly to lengthen them.

The persuasion now current as to the necessity of using sedulously the various dietetic and hygienic means of strengthening the system, which experience has sanctioned, in youth, in manhood, in age, must also have its influence. The means to this, and which in former times were within the reach of the wealthier classes of society alone, are now becoming common.

The important influence which the functions of the skin exert upon the very highest operations of the organism, is now acknowledged, and the increase of habits of cleanliness, as mere matter of propriety, has undoubtedly contributed much to the preservation of health: the use of soap, now universal, was all but unknown between two and three centuries ago†. Habits of cleanliness are regarded, not without good reason, as among the most precious gifts of civilization.

With the extension of better views on the circumstances and conditions that influence the general weal, the

anxiety to make them known, and the eagerness to carry them into practice, have gone hand in hand. These important words now find universal acceptance: "Whatever preserves health, serves society; for sickness, besides its vexation, occasions a loss of property, and a loss of time, and often it involves both the property and the time of others*." It is now almost everywhere held matter of moment, by wide streets, sufficient sewerage, and the discontinuance of sepulture in the midst of the dwellings of man, and even within the buildings dedicated to the service of the Creator, to secure due ventilation, and to keep the air sweet and wholesome. As the peace of nations becomes assured, let us trust that the high walls of fortified towns will be levelled, the pure air of heaven admitted to their inmost recesses, and the foul and marshy ditches which surrounded them, filled up and planted, become the means of delightful recreation and of health to their inhabitants†.

The facilities for procuring wholesome food are now so great, that diseases which in former times spread over extensive tracts of country, from sheer want of aliment fitted for the use of man, are now unknown. Through the progress of agriculture, almost every spot of earth is rendered useful, and the produce of our lands is vastly increased and is still increasing. The cultivation of the potatoe, of fresh vegetables, and of various kinds of useful fruit, the apple, the plum, the chesnut, and the orange in the different countries of Europe, materially repress the price of wheat, and have an unexceptionable influence on the health of communities‡.

* Ensor on the Population of Nations. Lond. 1818.

† What excuse shall we find for the foolish inhabitants of Paris, who in the middle of the 19th century have immured themselves, and pointed a battery from every height in the vicinity of their city, at their own hearts? Verily, science and cleverness are not good sense and foresight, or our friends of the banks of the Seine would never have been guilty of the egregious act of childish folly which they have just committed. But children, in the pains they take to build up houses of cards, have generally a looking to the enjoyment they are to have in knocking them down again, and so we must needs presume have the Parisians.—*ENC. ED.*

‡ Two centuries ago a salad was not to be bought in the markets of London for money; a

* Camper has treated of this, among other useful matters, in his Essay on the best Fashion of Shoes,—a work that should be better known than it is.—*ENC. ED.*

† Soap was first made in London in 1554. Up to this time it was one of the articles of import.

Adulterations of articles of food are now much rarer than they were*. The use of lead in glazing articles of pottery that are to serve as kitchen utensils, the art of tinning copper vessels, and even of coating them with a layer of insoluble enamel, are all improvements that have their influence upon the average life of man. Accidental poisonings are every year becoming more and more uncommon: within doors cast iron and tin plate have almost superseded copper, and without, poisonous plants give place to those that are useful; or the characters, and names, and deadly qualities, of such as still exist, being known and taught in every village school, accidents from them are very rare. The sale of poisonous articles, whether of mineral or vegetable origin is also more restricted than it was; it is

also in better hands, viz. those of the chemist and druggist, and therefore less liable to abuse. Does an accident by poisoning now occur? Immediately experiments are made and antidotes are discovered. The great perfection of chemical analysis, too, has rendered the detection of almost every variety of poison that can be introduced into the body of man, a matter of such easy certainty, that an attempt upon a fellow creature's life by poison is almost necessarily discovered, and the repetition of such practices of course most powerfully discouraged.

The care that is taken of the poor and helpless in almost every country of Europe, is another important feature in our modern civilization; and the benevolent solicitude of private associations in most of our larger towns to provide firing for the poor during the severer months of the year,* as also to furnish convalescents from serious illness with proper food, and parturient women and new-born infants with suitable articles of clothing, all tends directly to the maintenance of health, and the prolongation of life, among our poorest classes.

The experiment of colonizing thinly peopled or absolutely uninhabited tracts of country within the boundaries of Europe, seems to promise permanent improvement and advantage to the human family, partly by ridding it here and there of a burthensome superfluity of population, but more by placing thousands of poor at once in a position to achieve comfortable independence for themselves, and by turning waste and unproductive solitudes, sources of pernicious effluvia, into fertile and healthy fields. M. Demidoff, in his *Travels in Southern Russia*, expresses himself in these words on this subject: "I am persuaded that pauperism, mendicity, and deserted infancy, may people these solitudes with vast ad-

cabbage stock and a carrot were unknown; apples were scarce, and never used save in the crude and unnutritious state. Sir Walter Raleigh and Admiral Drake might have brought half a dozen oranges for the Queen's table, but the community had never seen the golden fruit of the Hesperides. At the present time we buy this fruit of the tropics at the rate of two or three for a penny in the streets of London! and through the blessing of sugar we are never at a loss for a meal for our children with an apple. Sugar is in fact one of the greatest conquests of man's industry, and the barbarism of making it a source of revenue, and regarding it as a luxury, ought to be abandoned; it is one of the prime necessities of life, and ought to be as free as air. It is little more than a century since the great bulk of the community lived upon salt provisions through the winter. Agriculture had made so little progress, that there were no green crops, no such staple as the turnip, not merely to keep cattle alive, but to fatten them, and so little hay was made, that it was always an object to save it for the use of the stock that must be maintained till the spring. The cattle which now supply us with fresh animal food through the whole of the winter, in our grandfathers' time would all have been slaughtered, and salted down at Michaelmas; there was no more fresh meat until God's providence brought round the spring. In Sydenham and Morton's times, and even considerably later than these, among the grand causes for which the assistance of medical men was sought, were the scurvy, and intermittent fever. The faculty would starve now did they depend on either one or other of these diseases. The death of the members of the community was then the source of professional income; now it is their birth. Juno Lucina is the true patron goddess of the medical profession in these days, not Apollo in his ire, and twanging his silver bow! ENG. ED.

* The high price of sugar, the consequence of high and discriminating or protecting duties, has unfortunately had the effect of establishing manufactories of sugar by a chemical process in the neighbourhood of London. There is one at Bow, where many tons per week are regularly produced, the whole of which pays duty to government—is a source of revenue to the state—and then goes to adulterate the sugar with which the poor man attempts to sweeten his tea, or to make his children's meal palatable, and additionally nutritious!—ENG. ED.

* Vide Moser (in the Prussian Medical Journal, No. 21, 1835,) and Quetelet (*Sur l'Homme*, &c.) who both show that in these countries the greatest mortality corresponds with the lowest temperatures, the least mortality with the highest temperatures. Taxes upon fuel must be held as equally barbarous and impolitic. The Corporation of the City of London raise a revenue of many thousand pounds per annum from the sea-borne coal that is consumed in the metropolis. No improvement that can be effected with the money so raised can compensate for the injury that is done by a tax so cruel, and that presses so unequally upon the rich and poor.—ENG. ED.

vantage to society, to public morals, and to themselves*."

The improved construction and police of prisons is another important point. These are now not merely places of detention and of punishment, where there was great danger incurred of contracting deadly diseases†, but schools of improvement: instead of proving, as formerly, certain means of confirming vice in its career, and corrupting innocence when suspicion led to temporary loss of liberty, there are now at all events the means proffered whereby the inmates may regain their moral with their personal liberty, and every pains taken, that innocence may quit them uncontaminated. Much difference of opinion still prevails in regard to the advantages or disadvantages of the several plans of treating prisoners that have been proposed. But the time cannot be far off when the friends of humanity will be enabled to arrive at unanimity of opinion on the subject. If experience prove that the American or solitary system is a frequent cause of insanity, it must of course be very much restricted or entirely superseded.‡

The milder punishments now awarded have also their influence in preserving the health of those who have made themselves obnoxious to the law. Mutilations, and other kinds of what may be called organic inflictions, have happily become matter of tradition in all policed countries.§

* M. Demidoff also thinks favourably of the "Colonial system for the cure of social evils" (pour la Guérison des Maladies Sociales,) which has been essayed in Holland. [There can be no doubt of the infinite advantages of the "allotment system" which is happily on the spread in England; the good that would certainly result from the general adoption of this system seems incalculable. Vide Mrs. London's very able book on Political Economy, 8vo. Lond.—Eng. Ed.]

† In former times the prisoners in Newgate and other large gaols, used to be decimated at intervals by typhoid fever of a bad kind, which was elaborately described under the name of jail fever, or jail diatemper. Epidemic fever is now unknown in any of the London prisons. In the House of Correction, Coldbath Fields, where there are usually from 1,300 to 1,400 prisoners, the infirmary has rarely more than three or four tenants at one time; and when I visited it in company with the author of this essay, there was but a single patient—a poor young woman far gone in consumption, which she was suffering under when she came into the place.—Eng. Ed.

‡ In Bernoulli (op. cit. p. 82) it is stated, on the authority of Coidet, that of 329, 15, or 1 in 22, had become insane.

§ All our experience seems to satisfy us nevertheless, that the grand object with society should be to take away inducements to commit crime: once a "criminal always a criminal" is an axiom with every one who has had to do with this class, whether in America or England, and it is probably the same in other countries. The "reform

In the military service harshness and severity are yielding every day—have already yielded—to humane and reasonable treatment. Attention to the cleanliness of his quarters, to the sufficiency of his clothing, and to the abundance and excellence of his food, added to humane and civil treatment, go so far to secure the common soldier against disease, that on home service he is probably the healthiest man in the community. It has been well observed by a very competent authority,* that "a good commanding officer has generally a healthy regiment." Thousands are still living, who have to thank the military hospital, and the skill and devotion of its medical officers in the English, French, and German armies, for health recovered, for life and limb preserved.

It is the same in the naval service. The sailor is now treated as a man and a christian; crowding in quarters is avoided; his provisions are of the best—in long voyages he is provided with preserved fresh meats and lemon juice; instead of being taught to acquire a taste for spirituous liquors by being forced to drink his allowance of grog, he is rather encouraged to abstinence, and all the evils that flowed from insubordination, the constant consequence of intemperance, are avoided. The ill effects of wetting between decks are now well known and never encountered; dry rubbing with holly stones is substituted for washing, and stoves are conveniently placed to secure ventilation; the ballast in all well-appointed ships is now some article that will not corrupt the air by its moisture and decomposition—it is pig iron, or, better still, large iron tanks filled with water, which afford the company a supply of that indispensable element, pure as when it came from the well, and almost *ad libitum*, through the whole course of even the longest voyage. The health of the navy has made truly wonderful progress within the last half century.†

of the criminal," they say, "is a dream." If this be so, our prisons might have Dante's lines over the gates of hell inscribed upon their doors:

"Lasciate ogui speranza

Voi che intrate qui."

"Leave hope behind, all ye who enter here!"

Eng. Ed.

* Sir James M'Grigor, Medical Sketches, Lond. 1804, p. 95.

† Vide Blane: Comparative Health of the British Navy from the year 1790 to 1814, in his Select Disserts.; and the Report on the Health, &c. of the Navy, by Dr. Wilson.

The special scientific study of the diseases of artisans and labourers, in laying open the often hidden sources of their sufferings, has, at the same time, exposed the ways and means of removing them, or rendering them nugatory*. The physician and philosopher working hand in hand here, good fruits have certainly not been wanting. The draught furnace, as a means of ventilating mines, and the safety-lamp of Davy, have already saved lives innumerable. Undertakings which, in former times, had all to be accomplished by the labour of men's bodies, and often proved highly detrimental to health, are now, for the most part, performed by means of machinery†.

If it shall be found that the mortality is actually greater in manufacturing districts‡ than in those where the population is chiefly employed in agriculture, it will, at the same time, be discovered that this is mainly due to inequality in the tide of occupation; that not unfrequently the stream of full employment and abundance is succeeded by the ebb of idleness and want. The advantages of savings banks, however, and of benefit societies, which

are ever better understood and more appreciated, promise gradually to lessen the consequences of this inequality. It is unquestionable that in the majority of the mills and manufactories themselves, with their roomy, well ventilated, and comfortably warmed apartments, the labourer is infinitely better off than he is in his dwelling-place, even though it be a cottage in the country*. To many of these magnificent establishments, too, medical officers are attached, so that disease is here nipped in the bud, and contagion is unknown.

The care that is taken of the sick poor, in public hospitals, whether maintained at the cost of the community, and out of the funds of the state, as on the continent of Europe, or by voluntary contributions, and at the expense of individuals, as in England, also contributes essentially to repress mortality. In former times these establishments were far from being the blessings which they are at present: in the Hôtel-Dieu of Paris in particular the mortality used to be frightful: but since every patient has been placed in a separate bed, and since cleanliness and ventilation have been held paramount elements in the police of hospitals, the mortality has fallen to a minimum, and, in the best regulated establishments, probably does not exceed its amount among serious cases in the houses of the opulent. Much, too, has unquestionably been gained by classifying patients, and distributing them to different wards, or even to different hospitals, both in a remedial and scientific point of view. It would be well, in every great town, to have a separate hospital for so infectious and deadly a disease as small-pox; for the important class of infantile diseases, for those affected with incurable diseases, for epileptics, for cutaneous diseases, &c.; and also distinct establishments for convalescents both in reference to bodily and mental infirmities.

The rescue and recovery of the apparently dead from drowning, exposure to irrespirable gases, &c., has

* See the work of Rammazzini on the Diseases of Artificers, translated into French by Patissier, and into German, with additions, by Schlegel; also, Adelman, on the same subject, Würzburg, 1803; Fuchs on the Influence of Trades, &c. on Health, in Hecker's New Annals; Turner Thackeray on the Effects of the principal Arts, Trades, and Professions, on Health and Longevity, 8vo. London, 1881; and Dr. Calvert Holland on Diseases of the Lungs from Mechanical Causes, 8vo. London, 1844.

† Ruptures are relatively much more frequent among the labouring than among the other classes of society. In Würtemberg it has been estimated that there are 30,000 persons affected with rupture. Riecke, p. 47.

‡ Quetelet, op. cit. p. 312. There can be no doubt of the fact being so. The mean length of life in Liverpool is 26 years; in some of the counties of England it is even as high as 55 years. But the defective police of the city from first to last, and the circumstances of the population, may be charged with the whole difference. In the city, hundreds, thousands, are suffered to herd in cellars below the level of the ground, and they are the most wretched of God's creatures: driven out in rags from their own country—Ireland—by starvation, they come to meet disease and death in the crowded avenues of Liverpool and Glasgow, Bristol and Manchester. But civilization can be rightly charged with nothing of all this misery; it is the barbarism of class legislation, against which civilization has been struggling in vain for centuries, that brings it all about. Thomas Carlyle, the philosopher, the poet, the friend of man, says, well and truly, that England has always treated Ireland like a step-mother, and that Ireland has requited her by sending her starvelings forth to degrade the hardy yeomen of the English soil to the level of the mud-housed, rag-clad, potato-fed outcast of the misgoverned country.—*Eng. Ed.*

* In the work of Legoyt, *La France Statistique*, d'après les documents officiels les plus récents, Paris, 1843, it is shown that in the seventeen departments of France distinguished for their industry and manufactures, the sanitary state of the population is much more favourable, than in seventeen others where industry is least.

not been left to the humanity and particular skill of individuals; the community has held the matter worthy of its attention; and, by their establishments under the name of "Humane Societies," their prizes, their honourable distinction of those who have saved a fellow-creature's life, as well as by spreading abroad in their "Instructions" better knowledge of the means adapted to the recovery of drowned or asphyxiated persons, many have been rescued who, without such help, would have been snatched away from existence before their time.

Contagious diseases have of late years lost much of their virulence, first, from the watchfulness with which measures of precaution and prevention are enforced, and then from the care bestowed in exposing and airing, in washing, in heating, and, if need be, in burning suspicious bales and articles in which infection might be supposed to lurk. May it not be that these wise measures have in fact rendered zymotic influences inoperative now, that in former ages proved pestilential? That the means taken to guard against contagion have, in fact, destroyed it? That diseases such as plague and yellow fever, contagious in past times, are contagious no longer? The discovery of chlorine and its preparations has placed a powerful weapon in our hands against corruption and contamination.

The careful and enlightened study of which the veterinary art is now made the subject, has thrown light on several serious and even mortal diseases which are readily transmitted from animals to man. Not to speak of hydrophobia, which has been known from remote antiquity to be an incurable disease*, we now know that the anthrax, or malignant pustule of the ox, and the affection closely allied to it, the tongue-canker, and, above all, glanders, are extremely apt to be inoculated upon the human subject, and to prove fatal when received. Knowledge of this kind of course leads to caution in the handling of diseased animals, and prevents the spread of their contagions. The tax upon dogs has also had a beneficial influence; the numbers kept are diminished, houseless and unowned animals are got rid of entirely;

so that in some countries of Europe it often happens that no case of true hydrophobia occurs for several years†.

The attention that has, of late years, been paid to medical topography, has likewise contributed much, and will undoubtedly contribute still more, to the eradication of the causes of endemical disease. The influence of particular localities, soils, and environs, upon the health of the community, and the measures calculated to repress or to annul whatever is prejudicial, have all been made the subject of careful study, and are now familiar to the medical men, the civil engineers, and even the statesmen, of most European countries. Wherever enlightened man spreads himself over the surface with his peaceful arts, his freer views and institutions, there the swamp and the tangled forest, and the damp and pestilence that brood over them in their natural state, disappear. Even as certainly does this ensue as its opposite: wherever the commercial and political weight of a community declines, where industry flags and population falls off, there do marsh and miasm, and their concomitants, disease and death, extend.—Neglect brings punishment in her train as surely as industry, and its sequence, improvement, lead affluence and long life in either hand‡.

No inconsiderable portion of the greater solicitude in regard to the public health displayed by government, as also of the better private information now extant on the means of guarding against disease, may be fairly ascribed to the appearance, in the countries of Europe, and in England especially, of so many excellent popular works upon the subject of hygiene; works composed by men of the highest attainments and most philosophic minds, conceived in the best spirit of enlightened philanthropy, and within reach of all in point of price§.

* Cless, *Topography of Stuttgart*, informs us that in the course of eighteen years but one case of hydrophobia had occurred in that city.

† See Macculloch's *Malaria*. London, 1837.

‡ Let me name with gratitude the writings of Dr. Andrew Combe (*The Principles of Physiology applied to the Preservation of Health*); of Dr. Southwood Smith (*The Philosophy of Health*); and of Dr. Thomas Hodgkin (*Lectures on the Promotion and Preservation of Health, delivered before the Mechanics' Institution*). Dr. Neil Arnott, too, has contributed largely, by his "Elements of Physics," and his tract "On Warming and Ventilating Houses," to make known the principles that lie at the root of

* Vide Levin on the Diseases of Domestic Animals which are transmissible to Man: Berlin, 1809.

The incessant war waged against erroneous views and prejudices affecting the public health, in lectures, newspapers, magazines, and special works, as it is still victorious, so does it extend the empire of improvement. The more the sanitary state of the community is threatened by misuses having their roots in ignorance and particular interests, the more loudly and incessantly must the better persuasion make itself heard. So long as the insanity prevailed, that sepulture in churches and chapels under the immediate protection of saints and martyrs, assured a state of blissful futurity to the souls of the deceased, the faithful, at their prayers, must needs inhale the vapours of the grave. A long series of years passed by before better knowledge sent the vital breath of heaven to blow with freedom through the damp and dingy city; superstition has long been on the wane, and sepulture of the dead among the living ought now to cease*.

It has but lately been discovered that the cruel practice of Suttee, in India, in which the widow burned herself upon the funeral pile of her dead husband, proceeded from no peculiar feelings of ungratified affection, from no strong sense of conjugal duty; so that government have felt authorized, on the strong grounds of reason and humanity, to interfere and discourage, and even to interdict, the sacrifice.

The times are not so very remote when diseases in general, or in certain particular forms, were looked on as punishments sent by God, to which we were bound to submit without resistance†. These have long gone by; or if, in some neighbouring countries, any such system of fatality still finds

accredence, it will very certainly disappear before the light of reason and humanity. It is never to be forgotten, however, that the first best gift which medical science has given to man—vaccination—was resisted and rejected, at first, on grounds both of religion and humanity: shall we venture to interfere with God's providence, it was said, or to engraft the humour of a brute upon the body of man? We now laugh at such insanity.

Many notions and practices in connection with disease, which were prejudicial, are disappearing gradually but certainly. The custom of keeping patients labouring under the acute exanthemata, — scarlet fever, measles, small-pox, — in a close hot atmosphere, was extremely injurious, and cost many a life†. The dread of cool fresh air is now happily overcome: the nursery and sick room are kept well ventilated; children are carried freely into the open air; and, the earlier months of life left behind, we do not fear to sponge and wash over our most delicate young with cold water, as a powerful means of giving tone to the system and strength to the limbs.

As the spread of true improvement has power to diminish disease, it may be fairly said that the increase of morality must have the same effect. Whenever society shall combine, and rigidly put down all gaming-houses, a fruitful source of disease will be dried up.

Every philanthropic society contributes not merely to the temporary and moral welfare of the community, but to its health and longevity. Who shall deny the blessed effects of our temperance associations, even where they are but partially in operation, and their influence may be supposed the least? To reclaim a drunkard is to effect the moral as well as physical salvation of a responsible being. What the educated man accomplishes over his inclinations upon principle and resolve, the ruder

almost all improvement; and Dr. Reid, in his elaborate work "On Ventilation," just published, has put the crown upon the subject.—*Eng. Ed.*

* Strange to say, it is in protestant England that this abomination has still its strong hold. Roman catholic France and Germany discontinued it long ago; and in Scotland burial in churches has been unknown since Knox's time. Mr. Walker, by his "Gatherings from Graveyards," though he has mixed the horrible and awful perhaps in too large proportion with his statements, has nevertheless done good service to the cause of true civilization. The parliamentary report on Intermment in Towns, and Mr. Chadwick's Commentary on it, complete our information on the debasing, demoralizing, and deleterious effects of the practice; and leave neither the legislature nor any interest in the community a shadow of pretext for suffering it to go on any longer.—*Eng. Ed.*

† See my work, "Origines Contagii," p. 121.

* Moseley, in his treatise on the Lues Cobilla, maintained that the practice of vaccination would be by and by people the country with a race of minotaurs! (Vide Baron's Life of Jenner, vol. i., page 353.)

† These are all occasionally very dangerous diseases. Small-pox has abated nothing of its malignity, and scarlatina is, from time to time, a deadly and, as it seems, altogether unmanageable disease. Measles is more rarely so destructive; but it often undermines a previously good constitution, and so cuts life short.—*Eng. Ed.*

less cultivated nature must become accustomed to by example and a pledge. Sobriety is the first, most indispensable basis of all improvement, the founder and preserver of human happiness. If these times succeed in rearing her an universal temple, they will have accomplished the most noble of destinies. The mortality among males in towns and in countries where intemperance prevails, is greater than that among females, mainly because their lives are more dissipated and irregular.

Life-insurance societies, and those institutions, such as savings-banks, where earnings not immediately wanted can be safely stored against the hour of need, all contribute to bodily well-being, as they tend to put the mind at ease, and secure it against the tear and wear of anxiety, the destructive consequences of change.

If it do actually appear that the condition of the lowest classes of society improves, undoubtedly the circumstance will have a material influence on the general sanatory state*. Many of the children of the poor, that look strong and lusty at their birth, dwindle away by degrees, and finally die; so that there can be no question as to the truth of the proposition, "in proportion as pauperism is rare, are infants reared†."

The larger and more commodious houses of modern times, in addition to the better clothing and food of the community, prevent the spread, as well as the production, of diseases. How many of the worst forms of sickness have their homes in the dens of privation and misfortune! Blindness is most frequent amongst the poorest classes,

not merely relatively but absolutely, and is owing, in the great majority of cases, to neglect and ignorance*. The chronic diseases of the eye, with which we see so many of the poor afflicted all their lives, are almost unknown among the middle and upper classes of the community.

A life passed in the open air, and hardening of the body by exposure, conduce, we will allow, to give it strength and durability; but when to these excessive toil is superadded, they immediately lose much of their beneficial influence. It is therefore indubitable that the simple natural state, as it has been called, is less favourable to longevity than the civilized condition. It has been ascertained, for instance, that women in the country have not such good lives during the years in which they are liable to become mothers, as those who live in towns. Want of proper assistance may occasionally be the cause of the difference, but there can be little doubt of its being mainly due to the bodily labour which country-women are so commonly required to undergo at a time when they require rest, and should be exempt from toil. The mortality in the country is certainly less than it is in great cities; certain diseases are also rarer there than in towns. The reason of this, however, is perhaps less to be sought for in the circumstance of crowding together, and the generation of gases and vapours which contaminate the atmosphere, than in the fact that occasions to commit excesses, to yield to courses that prejudice health, and shorten life, are here more numerous†. But the better these are known the more generally their pernicious influences are recognised, the more emphatically do the educated, and benevolent, and well-disposed, direct their

* The state of the poor in Great Britain has been variously estimated, according to the point of view from which it has been regarded. The well-informed and unprejudiced observer, however, sees it bettered on the whole, and holds the conclusion of Buret (*De la misère des classes laborieuses en Angleterre et en France*, Paris, 1841) when he says, "France is poor, England is miserable," as impressed with the seal of twofold exaggeration. [The state of the English very poor has commonly enough impressed the foreigner very disadvantageously; an intelligent and kind-hearted German gentleman, Mr. König, who knew England well, used always to maintain that it was "the heaven of the rich, but the hell of the poor." Other countries may be, doubtless are, the same; to me there has always appeared too much of truth in the observations of M. König.—*Eno. Ed.*]

† Lichtenstein, *On the Causes of the Great Mortality of Children in the First Years of Life*. St. Petersburg, 1837.

* Bernoulli, *Populat.* p. 86.

† As Farr conjectured in the First Annual Report of the Registrar-general of Births, Deaths, and Marriages in England, Lond. 1839. In the excellent review of this work in *Forbes's British and Foreign Medical Review*, Vol. IX. 1840, it is observed that from the above statement we might conclude that civilization, by the side of so much whose tendency is to prolong life, brings one of vast power to curtail and destroy; that among man's elements of longevity civilization fosters one mighty element of destruction; but immediately afterwards it is shown that a closer view of the circumstances that influence the mortality of large towns leads to the conclusion that true civilization, far from having any part in them, rather strives against them, and successfully resists their tendencies.

minds to abate them in their ill effects, or to remove them entirely.

The mortality among the upper and middle classes is not only smaller than among the very poor,* because there comfort or superfluity, here want is at home†, but also because amongst the rich, cleanliness is more attended to, and moderation is more in vogue. It is well worthy of remark, that in England, where unquestionably the greatest amount of material comfort prevails among the community, the greatest mean duration of human life, namely, 38 years, also occurs‡: in Russia, on the contrary, it is no more than 21 years§. The man in comfortable or affluent circumstances does not only live better; he lives longer.

But the means of preserving health, and of recovering it when lost, are made every day more accessible to him who is less favoured of fortune, whilst commerce has made it more easy to procure medical substances of every description. It is no trifling recommendation of modern medicine in its progressive improvement, to say, that it has discovered at once more powerful and less costly medicines than were in former use. Before the discovery of bark, how long must the sufferer from ague or intermittent fever have been laid up useless, incapable of all exertion, how often was he the victim of the consequences of this once universal disease! but how certainly is he now restored to himself and society by the discovery of the vegetable alkaloïds! A labouring or handicrafts man

who in former times was thrown out of work by the palsy of the hands and arms so familiarly known to follow poisoning with lead, was extremely apt to become for life a burthen upon, instead of a help and a stay to his family: with the assistance of strychnine and the sulphur bath the physician now sends him for the major part speedily back to his calling, his hands and arms restored to their former vigour and usefulness. Nor must the better education, the higher skill, of the present race of medical practitioners, be overlooked; it is impossible that this can be without effect on the mortality through accidental disease. To say nothing of the large share which the medical practitioner has at all times had in initiating sanatory measures, in enforcing and in spreading abroad information on hygiene, he now very constantly discovers, and nips in the bud, diseases that once allowed to get head are almost certainly fatal. Save in England, and here and there in Germany quacks and pretenders to medical science, without preliminary education, are no longer suffered. In France society has outlived the quack-salver, if it has not quite outlived quackery.

[To be continued.]

HISTORY OF THE DISCOVERY OF THE TRUE THEORY OF MENSTRUATION.

To the Editor of the Medical Gazette.

SIR,

WILL you permit me to call the attention of the readers of your journal to the following statement, made in a review of Dr. Lee's Lectures, in the last number of the London and Edinburgh Journal of Medical Science, p. 325: less, however, with a view to commenting upon the statements there made, than to serve as a means of laying before the profession a *faithful* statement of the progress of discovery in that interesting subject—the physiology of the female sexual system.

In the periodical just mentioned, the reviewer, speaking of Dr. Lee's work, says, "The author combats some of the generally acknowledged theories of menstruation, and concludes by stating that "the determination of blood to the uterine system, which takes place every

* Quetelet, l. c. Moser (Laws of the Probable Duration of Life, Berlin, 1830) shows that the results we have in reference to the mortality of the affluent are not quite satisfactory, inasmuch as they are obtained from registries of deaths alone. He says, p. 154, "In these days the influence of affluence is estimated somewhat too highly."

† Lombard, in Ann. d'Hygiène Publique, July 1835, showed that poverty had great influence in abridging life.

‡ Hawkins's conclusion (op. cit. p. 30) is fully borne out by the facts, when he says, "The man of affluence, the pauper patient of an hospital, the soldier and sailor on active service, the prisoner of war, the inmate of a gaol, all enjoy a better tenure of existence from this country than from any other of which we have been able to consult the records."

§ Cooper, Duration of Life, p. 23. An observation of Villermé in connection with England is this: In Archangel, between 1809-1827, there were 15,017 births, and 13,323 deaths. In the course of 18 years, therefore, the deaths exceeded the births by 8,306. In England, on the contrary, for every 100 deaths there have long been very regularly 101.33 births, so that the population doubles itself every 73 years.

month, and all the phenomena of menstruation, depend upon the ovaria; and that, at each period, a Graafian vesicle bursts, and its contents escape.* (See page 40.) In support of this statement he refers to cases in which, from the absence of the ovaria, whether congenital or otherwise, no attempt at the menstrual evacuation occurred; contrasting them with others wherein those organs existed, and the uterus was wanting, and yet in which violent pains, and all the other symptoms of menstruation, except the actual discharge, manifested themselves every month. The most convincing proofs adduced by Dr. Lee of the phenomena of menstruation being dependent upon the causes specified, are to be found in the recital of six cases, in which he was afforded an opportunity of seeing the parts of females who had died whilst menstruating. The first of them was seen so far back as 1831. *We are thus particular in the date, because certain Frenchmen are greedily contending for priority in a discovery which is more justly due to Drs. Power and Girdwood*.* In all the six cases enumerated by Dr. Lee, a ruptured opening in the peritoneal coat of one of the ovaria was observed, which led either to a Graafian vesicle on the point of bursting, or to a cavity which lately held the contents of one. Since the publication of these observations, Gendrin, Negrier, Jones, and others, have witnessed similar appearances. Indeed, so far back as the year 1797, Dr. Cruikshanks observed the same phenomena; but, as Dr. Lee remarks, there is no observation made in Dr. Cruikshanks' paper from which it can be inferred that he supposed all the circumstances of menstruation to depend upon the state of the ovaria; and therefore, although we must give Cruikshanks the merit of being the first who observed the fact, we cannot withhold from Drs. Girdwood and Power the credit of being the first who propounded the theory of menstruation being dependent upon the periodical development, maturation, and bursting of a vesicle in the ovary, whereby a sanguineous flux is determined to the genital organs. We are of opinion that the facts adduced by Dr. Lee, in support of this theory, if sanctioned by the observations and

concurring testimony of other equally respectable authorities, will not only render it the most plausible and satisfactory theory which has hitherto been brought forward on the subject, but will go far to render it incontrovertible."

M. Gendrin is doubtless the "greedy Frenchman" here alluded to; for, in 1839, M. Gendrin published, in his *Philosophical Treatise of Medicine*, an account of five dissections of women who died during menstruation, in each of whom he found a Graafian vesicle ruptured. The author of the preceding remarks has taken particular pains to fix the date of Dr. Lee's first dissection (March 1831), but he has avoided altogether mentioning the time when M. Gendrin is said to have made his first dissection, which, from the following history, it would appear was the 8th of February, 1828. "Une femme de 30 ans, chez laquelle on avait remarqué un certain degré de dérangement des facultés intellectuelles aux époques des règles, fut trouvée pendue à la triangle de son lit, le 8 Février, 1828; son mari déclara qu'elle était à l'époque de ses règles," &c. When the other four cases occurred M. Gendrin does not mention. M. Gendrin states that, for many years, he had neglected no opportunity, at the Hospital of La Pitié, of ascertaining the condition of the ovaria prior to puberty—after menstruation had ceased at the critical age—in women who had menstruated regularly—in those who had the catamenia interrupted—and in those in whom suppression had been the result of chronic disease. M. Gendrin concluded, from the whole of his elaborate researches, that menstruation is only a periodical phenomenon of a function which commences at puberty and terminates at the critical age; this function consisting in the production and development of vesicles in the ovary: it brings periodically a vesicle, and consequently an ovum, to maturation on the surface of the ovary, either to be expelled or destroyed by the rupture and inflammation of the vesicle. This last act being the termination of the formation and evolution of each vesicle, and of the ovule which it contains, cannot be continuous; it is accomplished at regular periods, and it is to this that the hemorrhagic turgescence of the whole genital apparatus is owing, of which the result is the

* Vide *Lancet*, Vol. 1, for 1843, page 825.

menstrual uterine hemorrhage. The general results of M. Gendrin's anatomical researches on the immediate cause of menstruation have been stated by him in the following words. "Toutes les recherches anatomiques dont les résultats viennent d'être exposés, établissent évidemment que l'hémorrhagie menstruelle n'est qu'un phénomène périodique d'une fonction qui commence à la puberté et finit à l'âge critique. Cette fonction consiste dans la production et le développement des vésicules dans l'ovaire; elle amène périodiquement une vésicule et par conséquent un œuf à maturation à la surface de l'ovaire, pour y être soit expulsé, soit détruit par la rupture et la phlegmasie de la vésicule. Ce dernier acte, étant la terminaison de la formation et de l'évolution de chaque vésicule et de l'ovule qu'elle contient, ne peut être continu; il s'accomplit à des époques régulières; c'est à lui que rattache la turgescence hémorrhagique de tout l'appareil genital dont l'hémorrhagie utérine menstruelle est le résultat." (Page 29, Tom. II.)

The disposition of the fallopian tube, adds M. Gendrin, found in his second dissection still connected with the ovary, during menstruation suddenly interrupted by the death of the woman—the known function of the organ being to receive the liberated ovum—the energetic association of the uterus and ovary, marked in this circumstance as in the case of conception by uterine turgescence, and even by a special organic effort or process (travail) at the surface of the ovary—the constant presence of a ruptured vesicle, and the state of evident inflammation on the surface of the ovary at every menstrual period—all these circumstances make us presume that on this occasion the fallopian tube receives the contents of the vesicle and transmits them to the uterus. The rupture of a Graafian vesicle, M. Gendrin affirms, occurs at each menstrual period, and not after fecundation alone, as Sir E. Home had asserted. The results of direct observations, continues M. Gendrin, on women who are menstruating, are confirmed by negative facts collected from women who were not menstruating, or who have ceased to be so physiologically, having reached the critical age, or by morbid causes: "ils sont concordants avec l'absence, reconnue

par tous les physiologistes, des vésicules de Graaf, et par conséquent des ovules, avant le développement de l'ovaire et la puberté, et avec la disparition de ces vésicules et des ovules après l'âge critique. La coïncidence constante de la menstruation avec la présence de ces organes dans l'ovaire établit une relation nécessaire de cause à effet. On voit par là pourquoi la menstruation indique l'aptitude à concevoir: elle est immédiatement liée à une fonction qui continue dans l'ovaire, et qui y amène tous les mois une vésicule et un œuf à maturation," p. 31*. M. Gendrin ingenuously acknowledges, that he never, however, detected the ovule expelled from the ovary, either in the fallopian tubes or uterus. In the account of M. Gendrin's Third Dissection, it is stated, that he found two vesicles in the ovarium ruptured. From this observation, he says, "Il paraît, qu'il peut se faire que deux vésicules du même ovaire arrivent en même temps à maturation et s'ouvrent simultanément. Cette circonstance, dans le cas de fécondation, expliquerait les grossesses doubles." It is obvious from this fact, that it must be impossible in any case to determine from the number of cicatrices on the surface of the ovaria how often a woman has menstruated.

"We are particular in the date," says the reviewer, "because certain Frenchmen are greedily contending for priority in a discovery which is more justly due to Drs. Power and Girdwood." As I have before stated, nothing was said about the date of M. Gendrin's first dissection, February 8, 1828, which if omitted intentionally was a culpable act. Having stated the results of M. Gendrin's researches on the ovaria during menstruation, published in 1839, let us now see to what extent he had been anticipated by others in this difficult and most obscure subject of inquiry, and what ground there is for the accusation here preferred against him and others of his countrymen.

* An account of what had been of late observed by Dr. Kerkringius, concerning eggs to be found in all sorts of females, is contained in the Philosophical Transactions for 1672. "Man," says Kerkringius, "hath his origin from an egg." "Though this opinion about the first formation of man in an egg, as that of all fowl, is not common, yet 'tis true." "These eggs are to be met with not only in the testicles of women married, but also in those of maids." "These eggs are of the bigness of a pea, and they contain a glutinous liquor, which will be hardened by the fire just as the white and yolk in other eggs. The taste of

In 1821, Dr. Power published an Essay on the Periodical Discharge of the Human Female, in which he defined the efficient cause of menstruation to be "an imperfect or disappointed action of the uterus in the formation of the membrane (decidua), which is requisite for its connexion with the impregnated ovum." "In the uterine system of the hen or pullet," observes Dr. Power, "the ova are found in every state of forwardness, without having been influenced by the male, containing the nutritive yolk and albumen, and possessing its crust, and only differing from perfect eggs in wanting the prolific contribution of the latter. In the frog, toad, and newt, as demonstrated by Spallanzani, and in fishes, the ova are perfected, as far as the female is necessary, without the assistance of the male, impregnation not taking place until they have been actually extruded from her generative organs. In vegetable generation the seed-pod or receptaculum contains the form, rudiment, and embryo of every

them is flat and unpleasant enough: they are invested with one or two fine skins, which stretch themselves a little while after the egg has fallen into the womb, and change into two membranes called amnios and chorion. And as the two membranes are always found afterwards enwrapping the child, so 'tis very probable that the eggs of women are also covered with two skins from their beginning, though by reason of their fineness I could not distinctly see them. It seems that Fallopius hath seen these eggs before me, as appears in his *Anatom. Observations*. And as to the use they have in generation, it seems easy to be determined, by reflecting on what that very expert anatomist, Thomas Wharton, teacheth in his *Treatise of Glandules*, ch. 38, concerning the manner of conception. For according to him, *semen viri penetrat in testes foeminae per uteri tubas*. Now there it is joined with the egg in such a manner which hath not been explained till now, but it is nevertheless certain and much resembling to what comes to pass in the other oviparous animals."

"The egg being thus *second* descends into the womb through the vasa deferentia, and in two or three days grows of the bigness of a black cherry. When they fall down, they are a little bigger than we have represented them, but being soft, they are easily flattened, and never remain round. If in falling they are handled and slightly pressed, there will stick a little skin to the finger, which shews that 'tis not seed, or anything like it; but of such eggs as we speak. *Fœmine deiciunt hæc ova imprimis tempore menstruorum, vel in iræ vehementia.*" The last paragraph has been quoted for the purpose of proving that Kerkringius knew that unimpregnated ova, by which he meant Graafian vesicles, were thrown off at the menstrual period, and it has been alleged that an attempt has recently been made to defraud Kerkringius. It will be seen that Kerkringius here refers entirely to ova after impregnation, and that he asserts, what is perfectly true, that abortion takes place, or that they are frequently thrown off from the uterus at the menstrual period, or during the violent excitement of anger.

future seed, even of the whole fruit, before the male organ is developed: as is beautifully demonstrated in the cucumber. Abundance of other instances might be adduced. The above are evidently the effects of a leading principle, which it is fair to infer is equally applicable to the human female. The mode of vivification of the embryo, and of the subsequent process of evolution in each individual, is to be regarded as a secondary and accidental circumstance, influenced by the peculiar structure of the animal. Thus, in birds, the ovum is matured by incubation; in fishes, by solar heat and moisture; while in the viviparous animals, the maturation is effected within the maternal system in a nidus termed the uterus. But the correct application of the above to the actions of the human female does not rest upon mere analogy. At and subsequent to the time of puberty, the enlarged ovaria are found to contain ova (?) in different states of perfection, and in women who have never been impregnated, corpora lutea, and cavities which have been supposed previously to have contained ova, have been detected; whence it may be inferred that, in them, not only the formation but the extrusion of ova is accomplished without the influence of the male. So far the analogy appears to be confirmed by facts admitting of demonstration, and which will scarcely be called in question. It will be attempted to show that menstruation is a farther link in the chain of these progressive actions, when they fail to be determined to conception by the operation of male influence." Dr. Power quotes the following passage from Dr. Cullen's *First Lines*, to prove "that the actions of the uterus at the period of puberty are influenced by the state of the ovaria. "As a certain state of the ovaria in females prepares and disposes them to the exercise of venery," says Dr. Cullen, "about the very period at which the menses appear, it is to be presumed that the state of the ovaria and that of the uterine vessels are in some measure connected together, and as generally symptoms of a change in the former appear before the latter, it may be inferred that the state of the ovaria had a great share in exciting the actions of the uterine vessels." Dr. Power does not notice the observation published by Mr. Cruik-

shank, in 1797, in a paper in the Philosophical Transactions, in which he says, "I have also in my possession the uterus and ovaria of a young woman who died with the menses upon her. The external membranes of the ovary were burst at one place, from whence I suspect an ovum escaped, descended through the tube to the uterus, and was washed off by the menstrual blood." There is no evidence to prove that Dr. Power ever examined the human ovaria during menstruation, to ascertain whether or not his hypothesis was well or ill founded. He furnished no direct proof of its truth from observations on the human subject; it rested solely upon analogy. "At, and subsequent to, the time of puberty, he says, indeed, the enlarged ovaria are found to contain ova in different states of perfection; and in women who have never been impregnated, corpora lutea, and cavities which have been supposed previously to have contained ova, have been detected." He adduces no fact to prove that these cavities actually contained ova, and he admits that they had merely been supposed to do so. But the existence of the unimpregnated human ovum was not demonstrated before 1827: when Dr. Power, therefore, asserted, in 1821, that ova escaped from the ovaria at each menstrual period, he made a statement for which he had no grounds: it could not have been applied to the real ova, which, as has just been stated, were not then discovered, and if he referred to Graafian vesicles, his statements were completely erroneous, because the Graafian vesicles are not discharged from the ovaria during menstruation, but remain after the function has been performed. Dr. Power, therefore, may be permitted to enjoy all the glory of propounding a theory, whilst it is remembered at the same time that of that theory he did not furnish one satisfactory proof. M. Gendrin, it is obvious from the preceding statements, both propounded and proved the truth of the theory; and yet, with other individuals equally distinguished, he is stigmatised as a "greedy, unprincipled Frenchman," contending for priority in a discovery which is more justly due to others.

There is no printed or published record of any observations having been made on the human ovaria during menstruation, either in this country or on

the continent of Europe, from 1797 to 1831, when Dr. Power's hypothesis had nearly sunk into oblivion. From the article on the Ovaria by Dr. Lee, which was published on the 1st of April, 1833, in the 3d Vol. of the Cyclopaedia of Practical Medicine, it appears that his first dissection was made on the 11th of March, 1831. The following is the account given of the appearances observed in this and three other cases which occurred to him in 1831 and 1832.

First Dissection.—On the 11th of March, 1831, we examined," says Dr. Lee, "the body of a young woman who died during menstruation, from inflammation of the median basilic vein. The left ovary was larger than the right, and at one point a small circular opening, with thin irregular edges, was observed in the peritoneal coat, which led to a cavity of no great depth in the ovary. Around the opening, to an extent of three or four lines, the surface of the ovary was of a bright red colour, and considerably elevated above the surrounding part of the peritoneal coat. On cutting into the ovary, its substance around the opening and depression was vascular, and several Graafian vesicles of different sizes were observed. The right ovary was in the ordinary state. Both fallopian tubes were intensely red and swollen, and their cavities were filled with menstrual fluid. The lining membrane of the uterus was coated with the same fluid, and the parietes were soft and vascular. The size of the uterus was not increased."

Second Dissection.—In the autumn of the same year, a woman under twenty years of age died suddenly, from acute inflammation of the lungs, while menstruating. The body was examined by Mr. John Prout, and the uterine organs were brought to us for inspection. A red, soft, elevated portion of the right ovary was also here observed, and at one part the peritoneal coat to a small extent had been removed; the edges of the opening were extremely thin and irregular, and in the substance of the ovary under the opening was an enlarged Graafian vesicle, filled with transparent fluid. Numerous small blood-vessels were seen running along the peritoneal coat of the ovary to the opening. When the substance of the ovary was laid open, several vesicles of various sizes, and at different depths,

were found imbedded in it. The free extremities of the fallopian tube were gorged with blood, their cavities were filled with a red-coloured fluid. The uterus was not enlarged, but the parietes were gorged with blood; and the lining membrane of the fundus was coated with menstrual fluid. A small coagulum of blood likewise adhered to the upper part of the uterus."

Third Dissection.—On the 2d of July, 1832, Sir Astley Cooper, to whom the writer had mentioned these cases, sent him the ovary of a woman who died from cholera while menstruating. The ovary was much larger than natural, and at one point there was a small irregular aperture in its peritoneal coat, through which a portion of a slender coagulum of blood was suspended. On cutting into the substance of the ovary, it was found to be occupied by three small cavities or cysts, one of which was filled with a clear ropy fluid, another with semi-fluid blood, and the third, which communicated with the opening in the peritoneal coat of the ovary, with a firm coagulum.

Fourth Dissection.—"On the 18th of November, 1832, the uterine organs were removed by Messrs. Girdwood and Webster from the body of a young woman who had died suddenly the preceding day, when the catamenia were flowing. Both ovaria were remarkably large, and both fallopian tubes were red and turgid. The peritoneal coat of the left ovary was perforated at that extremity which was nearest to the uterus by a circular opening, around which aperture, for several lines, the surface of the ovary was elevated, and of a bright scarlet colour, like extravasated injection; the margin of this opening was thin and smooth, and did not appear to have been produced by laceration. Its centre was slightly depressed below the level of the edges, but there was scarcely the appearance of a cavity beneath. The right ovary was much larger than the left, and when cut into, a cavity or cyst was found, which was filled with half-coagulated blood. The peritoneal coat of this ovary was entire. The uterus was large, and when cut into the parietes appeared to contain an unusual quantity of blood. The inner membrane was of a bright red colour, and coated with a thin layer of catamenial

fluid. Both fallopian tubes were red and turgid, and the interior of the left was filled with menstrual fluid, but nothing in the form of a Graafian vesicle could be detected in the tube. The appearances now described have been accurately represented in a drawing made from the parts within two hours after they came into the author's possession."

Dr. Lee propounded no theory of menstruation from these facts, but concluded with the following simple statement, which even now seems to comprehend all that is yet positively known on this subject; viz. that the determination of blood to the uterine system, which takes place every month, and all the phenomena of menstruation, depend upon the ovaria, and that at each period a Graafian vesicle bursts, and its contents escape.

"We cannot withhold," says the reviewer, "from Drs. Girdwood and Power the credit of being the first who propounded the theory of menstruation being dependent upon the periodical development, maturation, and bursting of a vesicle in the ovary, whereby a sanguineous flux is determined to the genital organs." Upon what authority is this award made? Of course, Drs. Girdwood and Power,—it was Power and Girdwood before—whom, one would fancy, were associated in their observations, published upon the subject, before Dr. Lee was heard of in the *Cyclopædia of Medicine*, of April 1833, or M. Gendrin had appeared in his *Traité Philosophique* in 1839. No such thing. Dr. Power's hypothesis, as we have seen, was given to the world in 1821; when does the reader imagine Dr. Girdwood appeared upon the stage—in 1820 or 1821, surely? No! In 1831? No. In 1833, that he might have at least a claim to dispute the thing with Dr. Lee? Still the answer is *no*. It was not till March 1843 that Dr. Girdwood published his letter on the *Theory of Menstruation* (*vide Lancet*, March 4th, 1843), to the right interpretation of which he has just as much claim as he has to the discovery of the circulation of the blood, or of the *Georgium sidus*. Publication by lecture or the press is the only acknowledged test of date of scientific discovery; but we see that Dr. Girdwood only appears four years after the publication of M. Gendrin's *Traité Philosophique*, and ten

after that of the article on the Ovaria, in the Cyclopædia of Practical Medicine.

But your readers will be able, from the following definitions of the human ovum and corpus luteum by Mr. Girdwood, to judge for themselves of his fitness to propound a new, or rather to re-propound an old theory of menstruation, and to discover, from his profound ignorance of the very rudiments of embryology, how impossible it was that he could have advanced this department of science. "The barbarous nomenclature in use by physiologists," observes Mr. Girdwood (Lancet, 4th March, 1843), "the same expression being used by different authors in different meanings, has been another grand means of obscuring this subject. 'Graafian vesicles,' 'ova,' are used as if they were different things. Then we have the 'corpus luteum,' 'the true corpus luteum,' 'the false corpus luteum,' the one the result of impregnation, the other something as yet not satisfactorily accounted for. . . . I may as well define what these expressions mean, and thus get over the pons asinorum of the subject." . . . "Ovum, corpuscle, Graafian vesicle, are different names applied to those bodies existing in great numbers in the ovary, not only in women, but in the ovaria of all females where the sexes are apart—terms all of them expressive of those oval bodies found so numerous and formed periodically by all females of all animals, discharged from the stroma of the ovary at maturity, and that maturation effected by the female herself, without any influence having been exercised by the male; in fact, an ovum, as here defined, containing a macula germinativa within a vesicula germinativa, and this surrounded by the yolk or nutritive material, adapted for the future development of an embryo, is the elaboration, as far as female influence extends, in preparation for the future being, and waiting only for the influence of the male as a stimulus to its development." It is humiliating to the British physiologist to know that such ignorant incoherent nonsense should have been penned and published in the year 1843.—I am, sir,

Your obedient servant,

ANGLUS.

WOUND OF THE DEEP FEMORAL ARTERY:

LIGATURE OF THE VESSEL, AND OF THE COMMON FEMORAL.

By JOHN CHARLES HALL, M.D.

Member of the Royal College of Surgeons of England.

(For the London Medical Gazette.)

BEFORE describing more minutely an important operation which I performed last week, it may render my explanation more plain if I recal to the recollection of the reader that the profunda femoris artery is given off about two inches, or two inches and a half, below Poupart's ligament, and ought to be regarded rather as a division of the femoral, than as one of its branches.

Probably the best description of these vessels we possess is that given by Murray, who describes the short branch of the femoral, below Poupart's ligament, as the common femoral, and its two divisions as the *femoralis superficialis*, and the *femoralis profunda*; the superficial femoral supplying the knee, leg, and foot, and the deep-seated profunda the thigh. With the above remarks I proceed to explain the operation performed by myself last week.

On Saturday night, March 31st, I was sent for, about half-past eleven, to the White Horse Public-house, East Retford. The landlord of the house told me a man had just been stabbed in the upper part of the thigh.* On entering the house I saw a man on the floor, covered with blood; there was an immense quantity of blood also upon the floor. Mr. Brew, the assistant of Mr. Davies, surgeon, was endeavouring to stop the hæmorrhage by pressing upon the trunk of the artery with a key. It was at once evident to my mind, on examining the wound, which was about two inches in length, that one of the larger arteries of the thigh had been wounded: my opinion at first was that the common femoral was the vessel wounded, and I at once proceeded with the purpose of securing it. On dividing the skin, it became clear that the knife with which the stab was given had passed from below upwards; the parts

* I have not mentioned, or alluded to, the nature of the case, as it will have to be decided by a Jury at the next Nottingham Assizes; a verdict of manslaughter having been returned against the party by whom the wound was inflicted.

had indeed been freely divided under the integuments, and I cautiously followed the direction of the wound. On removing the coagulated blood from its cavity, a slight oozing proceeded from the wounded vessel, and on Mr. Brew for a moment relaxing his pressure, a jet of blood flew from it. Enlarging the wound I came to the first portion of the artery, where the common femoral divides into its superficial and deep branch. I requested Mr. Davies to sponge away the blood, and then pointed out to this gentleman and Mr. Brew, a wound in the profunda, close to its origin, and passing upwards into the common femoral. I passed a ligature round the femoral, above the part where it was wounded, and above the origin of the profunda, another below, and another on the profunda, below the part where it was wounded: these three ligatures effectually stopped the bleeding. The man did not lose much blood during the operation; there was a little bleeding from a vein (probably the profunda femoris) which was restrained by pressure; the wound was cleaned with a sponge and a little cold water, and after a time closed by a few points of suture and some straps of sticking plaster: the limb was supported with a bandage covered with flannel, and the poor fellow placed in bed. Some brandy and water was given, and every attention paid to him. We could even now hardly detect any pulse at the wrist; he gradually got more feeble, and died at two o'clock on the following day, about twelve hours after he was wounded, evidently from the great quantity of blood lost before the arrival of Mr. Brew and myself: the man was surrounded by a pool of blood when I saw him first, and must have lost many pints. On examination after death, it was seen that the knife, (the blade of which was said to have been more than six inches in length) had passed from below upwards, and had entered both the profunda and the common femoral.

Remarks.—The above important case suggests the following remarks on the treatment of wounded arteries. In by far the greater number of cases of hæmorrhage from a wounded artery, we cannot wait for the usual natural processes by which bleeding is arrested, but must have recourse to immediate and certain means. In a division of

the smaller arteries pressure may be sufficient, but in wounds of the larger vessels a ligature well applied is the only means that can be relied on. It is necessary to secure both ends of the wounded artery.

In the unfortunate case just described, both the profunda and common femoral had been penetrated, and it was therefore necessary to place the ligatures in the manner already described; for Mr. Hodgson has remarked that the necessity of tying both ends of a wounded artery is evident from the fact, that the anastomoses in all parts of the body are so extensive, as to furnish a supply of blood which may pass through the lower extremity of the wounded vessel in a sufficient stream to produce an alarming, and, in some instances, a fatal hæmorrhage* ;” and Mr. Liston,† that it will not be sufficient to include the vessel above the wounded point, for the lower part will, after some time, be supplied with blood by the collateral branches, almost as freely as by the large trunk, and consequently bleeding will be renewed. Two ligatures are to be employed, one above and the other below the wound.”

The observation of Mr. Hodgson is proved to be correct by a case he mentions, in which death was caused by great loss of blood from the lower end of a divided brachial artery. Of course the inference is clear that both ends of the vessel ought at once to have been tied on the receipt of the wound. It has been suggested that in a case in which it was difficult to get at both ends of the artery, the trunk may be tied in a part of the limb where it can be easily exposed; for example, in this case of the wounded deep femoral, it would have been much more easy to have cut down at once upon, and secured, the common femoral high up in the thigh, than to have followed the course of the wound and secured the profunda. The case just quoted from the work of Mr. Hodgson is a sufficient answer, and in speaking of this practice, I find, he says, “it was falsely deduced from a knowledge of the fact, that the ligature of an artery at a distance from the disease will affect the cure of an aneurism. But a more inti-

* On Diseases of Arteries, &c. p. 469.

† Elements of Surgery, art. Wounds, p. 236.

mate acquaintance with the condition of a limb after such an operation, and the processes by which the cure of an aneurism is effected after the modern operation, afford a complete illustration of the inefficacy and danger of this mode of treating a wounded artery; for it is now fully proved, that, when an artery is tied, a stream of blood continues to pass through it below the ligature*." In some well authenticated instances, however, success has attended the application of a ligature to the upper end of a wounded artery only, (Mr. Hodgson and Mr. S. Cooper both allude to them), the patient having recovered without bleeding from the lower orifice, which appeared to have been closed by the natural processes. It is an experiment which I should never try, and we may content ourselves by quoting, in reference to this part of the subject, the words of that experienced surgeon, Mr. Liston:—"Cases of hæmorrhage," he says, "have occurred, in which the tying of the vessel immediately above the wound has been successful; but these are few, and by no means afford any argument for the adoption of such a measure†."

The occurrence of this unfortunate case brought forcibly to my mind these words of Mr. S. Cooper:—"As a bleeding vessel admits of no delay, and the preservation of his life entirely depends upon proper measures being immediately taken, no man ought to be suffered to profess surgery who is not competent to the treatment of wounded arteries, whether injured by accident or in a surgical operation. Loss of limb, or life itself, is the too frequent consequence of such ignorance." It is a comparatively easy task for a surgeon of good nerve, even when only moderately acquainted with the anatomy of the part on which he is about to operate—in the theatre of an hospital, surrounded by a brilliant medical staff, having a good light, proper instruments, and all other appliances—having had time to think over, to consider each step of the operation some days before performing it, to cut down upon an artery and secure it. But these are not the only circumstances in which the surgeon must expect to be called upon to operate. He must also be ready at a moment's notice, with the kitchen of a beer-house

perchance for his theatre; a floor deluged with blood for his operating table; his only light a couple of tallow candles, and a crowd of drunken men, not easily prevented from pressing upon him when operating, for his spectators. In conclusion, I have to express my sincere thanks to Mr. Brew for the coolness and patience with which he seconded me, and also to Mr. Davies, for his valuable assistance in the course of the operation.

East Retford, April 3, 1844.

EFFECTS OF OPIUM ON THE CATAMENIA.

To the Editor of the Medical Gazette.

SIR,

IN the number of the MEDICAL GAZETTE for the 16th of March, is a paper taken from the New York Journal of Medicine, written by Dr. James M'Cune Smith, which commences with the following quotation:—

"Pereira observes that we have little positive information as to the effects of opium on the reproductive organs of women: it is said that the catamenia, lochia, and secretion of milk, are unaffected by it; whence he infers, that its use in the female is not likely to be attended with suppression of the uterine or mammary functions." Dr. J. M. Smith then goes on to refer to certain cases which had fallen under his notice within the last four years, and which give uniform evidence contrary to the above view. The cases are five in number, in all of which the catamenial discharge was suspended by the habitual use of opium.

It is somewhat singular that my own experience, extending over a period of somewhat more than thirty years, is directly opposite to that of Dr. J. M. Smith, and I think it but right to state the fact, as some of my professional brethren might be led to confide too implicitly in the power of opium to suppress the catamenial discharge, whereas I do not recollect one case in the whole course of my practice in which such an effect was unequivocally produced: I have, on the contrary, known many where the catamenia returned under the use of opium. These were more especially cases of gastrodynia, occurring in young ladies, and

* P. 471.

† P. 237.

also of difficult and painful menstruation, where an opiate acts like a charm in relieving the spasm and inducing a free flow of the discharge. But to come more immediately to the point—that is, to the habitual use of opium—I have at this present time a patient who for some years has been in the daily habit of taking large doses of black drop, and for the last two years several grains of the muriate of morphia in addition: at the present time I find her daily dose is one entire bottle of black drop, and eight grains of the mur. morphia. This lady is 45 years of age, is unmarried, but labouring under a disease which occasions her great suffering, and yet up to the present period no suspension of the catamenia has been produced.

I will extract two other cases from my note-book, in both of which the quantity of opium taken daily for a series of years was very considerable, and no suspension of the catamenia was the consequence. But the object of my recording these two cases was, the effect which I supposed the large and long-continued doses of opium to have produced upon the gestative powers of the uterus, each of these ladies having, after marriage, borne one healthy child at the full period, and afterwards having each produced several children at the periods of six, seven, and eight months, feeble and emaciated, and none of which lived beyond a few hours. The first of these ladies, when only sixteen, consulted a practitioner on account of spasms at her stomach: he directed her to take twenty drops of laudanum when the attacks came on; it however, soon became necessary to increase the dose, and the use of opium by and by became a daily habit. She consulted me previously to her marriage. She was then twenty-six years of age, and her daily quantity of laudanum was six ounces. Vain attempts were made to overcome the habit, and she died in her fortieth year, the catamenia occurring regularly during the whole of that period, excepting whilst pregnant.

The second of these ladies, when I knew her, was married to her second husband; it was during the life of her first that she acquired the habit of taking laudanum, and at the time I speak of the quantity was enormous—not less than 12 oza. per diem; not-

withstanding which, the catamenia occurred regularly, and she bore one healthy child, and afterwards had a succession of miserable premature children: she died at the age of 44. I could, were it necessary, adduce many other cases to show that the functions of the uterus are not usually suspended by the use of opium.—I am, sir,

Your obedient servant,
EDWARD GREENHOW, M.D.

North Shields, April 24, 1844.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

Practical Observations on the Prevention, Causes, and Treatment of Curvatures of the Spine, &c. By SAMUEL HARE, Esq. Surgeon. 2d edit. pp. x. and 177, royal 8vo. Churchill.

THERE are various classes of books, of medical books especially: some, the purpose of which is to give the world new information; these are A, No. 1 books—*rari nantes in gurgite vasto!* Others, the business of which is to give connected and collected views of particular subjects; to criticise all that has been advanced upon them under the guidance of sound physiology, pathology, and therapeutics; and to draw general inferences for the information and guidance of those who have less experience, less learning, and less leisure than the writers; these constitute A, No. 2 books. There is a third class of books which, if they neither contain aught that is new, nor display anything like research or learning, or experience, are still within the pale of endurable books; they are the offspring of the younger members of the profession, men of liberal education, anxious to try their pinions, and who, without stooping from their rank as scholars and as gentlemen, are desirous of making their name and whereabouts known to the world. These are a better kind of inaugural dissertations, not altogether culled from the professors' note-books. They form the B class; their authors will rise, and get into one grade or another of the A class by and by.

There is a fourth class of books, which carry the black flag unblushingly stamped on their cover and title; they are the productions of ignorant

empirics, and openly profess quackery. These books are No. 1 of their class; but it is a very low class—among the last letters of the alphabet.

The fifth and final class of all comprises those books that, under friendly colours, entice unsuspecting strangers to come within range of their guns, and to speak them; they even invite the strangers on board, and set meat and drink before them, which seem wholesome fare enough; but woe to the unwary partaker!—the meal is “mandragora,” the drink is “eisel.” These constitute the Z class of books, and there is no grade in it. Such books are the products of members of the profession, regularly received, duly qualified to practise, but who have fallen away from their oaths and the high destinies to which they were called; who, out of an incongruous mixture of science and ignorance and a purpose to deceive, prepare a mess which, utterly rejected by the professional stomach, has nevertheless been found, by long experience, to accord well with the digestive powers of the community.

How ought we in our independent critical capacity to entreat these different classes of books? The first and second we of course take to our bosom, and love and cherish; the third we do not reject—the child creeps before the man walks erect. The fourth we ignore; the fifth we hold as adders fanged, and feel it to be our duty to do our best to strangle them—at all events to extract their sting, and make them harmless.

Mr. Samuel Hare's book is a very pretty specimen of our third and fifth classes combined. It has a decidedly juvenile, a green aspect—class the third; but then its pictures of the table like a rack, and of the crooked spines, and the general tone of the text, give it unquestionable claims to a place in our fifth class. In his preface to the first edition, Mr. Samuel Hare tells us that “the great increase of spinal distortion, particularly of late years, and its alarming prevalence at present, together with the various and discordant opinions which have long existed as to the causes of the disease, and the most efficacious plan of treatment, will, it is presumed, furnish a sufficient apology for the publication of another treatise on the subject.” We deny that these reasons will have any such effect. If

S-like back bones be common, the cause or causes of them are perfectly well understood; and if there be one point in surgical therapeutics more than another upon which unanimity of opinion prevails, it is in regard to their remedies.

Mr. Samuel Hare proceeds:—“The author's attention has been particularly directed to the study of this disease, from the circumstance of his having been, some years ago, afflicted with a morbid sensibility of the spine, during the progress of which his sufferings were very considerable, and necessarily productive of great inconvenience.” This is an old trick; our friend Charles Dickens would have written “dodge”—*quaque ipse*, &c.; of course, no one so competent to write practical observations on the prevention, causes, and treatment of curvatures as he who has himself suffered from “a morbid sensibility of the spine, during the progress of which his sufferings were very considerable, and necessarily productive of great inconvenience.” Who the devil would doubt it?

But we are recalled by the profane word that has just dropped from our pen, to the recollection that we have—we surely must have—a saint in hand. He begins his introduction in a pious strain:—“The human body,” he tells us, “exhibits indubitable evidence of consummate skill. . . . None but a Being, whose essential attribute is boundless benevolence, could have originated a performance so benevolent and complete.” Originated a performance so benevolent and complete!—the human body a *benevolent* performance!—complete, granted; but how benevolent? Let us go on:—“In the splendid chain of animated existence unfolded to view by the master-hand of nature”—Mr. Samuel Hare obviously here confounds the work with the Creator, the effect with the cause; or he calls nature God, which orthodox Christians say is Atheism; but we acquit Mr. Samuel Hare of any such impiety as this. To proceed:—“Our view is indeed limited in its range, and obscure in its perception; nevertheless it exhibits”—he means perceives—“an almost endless variety of beings, rising one above another in the scale of progressive gradation; displaying different degrees of corporeal and instinctive excellence; and terminating in him-

self,"—himself—who? Our view is limited, nevertheless *exhibits* degrees of excellence terminating in *himself*—we follow without break—"himself,—being vastly superior to the rest in intelligence, and the delegated master of them all." Now this is obviously not addressed to the profession, but is driving asinine cant. No one who deeply feels, and truly understands God's handiwork in his creature man, writes in such a strain; he who does so has no title to a hearing on the subject from his brethren.

With the samples already given our readers will not of course expect to find anything worth noting in the book, the form of which, in fact, shows that it was not intended for the profane professional reader; it is a magnificent royal octavo, inclosing good typography upon the best of paper, within handsomely embossed boards; and very certainly, or we mistake Mr. Churchill's clear-sighted apprehension of the relation betwixt cause and effect—*cause*, publication of Mr. Samuel Hare's book; *effect*, loss of money by the business,—very certainly the private speculation of the author himself. Him it will cost money; but it will do to advertise, and there be fools enough in the world from whom he may reasonably hope to win his money back again. The book is not intended for our profane hands; we only trust there is no scrap of any sentence in what we have written which Mr. Hare can detach from the context and twist into an approval of his labours. How he should have sent us his book at all we do not understand. We trust we have satisfied him that it has fallen into not unmindful hands.

Is Samuel Hare, Esq. quite sure that these pictures of distortions—monuments of the effects of his treatment—are always placed in their proper sequence? Ought not 1, 2 occasionally to be to 2, 1; 2 being the back before it was put to the question, 1 the back after the torture? We have seen patients made *straight* enough, God knows, by such procedures as Mr. S. Hare advises; but they never could walk afterwards. They were straightened; but it was much as Mr. Mould would have straightened his subjects; and they had to become dependent to the end of their lives for the treatment which that respectable gentleman only

looked to bestow once upon any individual, and that when he was done with life: they had to be carried about upon their backs to the end of their days.

MEDICAL GAZETTE.

Friday, April 26, 1844.

"Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO

THE GRINDING SYSTEM :

ITS CAUSES AND REMEDY.

No. II.

In reflecting on what we wrote in our last upon this pernicious system, we see more and more clearly that the grounds we gave for the practice are the true ones. — To grind for the Apothecaries' Hall is universal; to grind for Surgeons' College is unfrequent; to grind for the office of house-surgeon to one of our great hospitals is unknown. The examination in no case extends over an hour; it is rare that it proceeds for more than thirty, thirty-five, or forty minutes. At Apothecaries' Hall, in this brief interval of time, the entire Cyclopædia, not merely of the strictly medical, but also of the accessory sciences, has to be gone over; occasionally, too, the Latin language is included. At Surgeons' College, anatomy, and the doctrines and practice of surgery, alone occupy attention. At our hospitals the practice of surgery is the principal or sole theme, with no more than a question or two, by the way, on anatomy.

We accede to the proposal without limitation, that members of the medical profession ought to be men of the highest education: they ought to be competent classical scholars; they ought to have a fair knowledge of Physics, Chemistry, and Natural History, including Zoology, Botany, and the commercial and chemical history of the

substances employed as medicines. But it is quite obvious that these various subjects have no immediate connection with the science and practice of medicine. He who is profoundly ignorant of the natural history of rhubarb, for instance, may still be a master in the art of prescribing it; he may be perfectly familiar with its effects, and appreciate to a nicety the circumstances in which it is indicated, yet all the while know nothing of its botanical position, of the course by which it arrives from the frontiers of China, over the deserts of Russia, and by the Baltic Sea, to the warehouses of the drug-merchant in Thames Street. Such knowledge ought to be possessed, but it ought evidently to be as a preliminary to the study of medicine, properly so called; it is too late a day, when a young man presents himself to be examined touching his knowledge of the structure and functions of the human body, of the derangements to which this structure and these functions are obnoxious, and of the means at command of abating or removing them, to be interrogated about the pentandria monogynia, and the like. No; let there be a preliminary examination in regard to all the sciences, which, however desirable, however needful, we will allow, are still no more than accessories; which have served but to prepare the mind aptly to receive, and duly to appreciate, the sciences which are properly, and in truth solely, medical.

A preliminary examination, then, by competent men, it strikes us, is the first and most necessary step to secure the public in the services of duly qualified medical attendants. And this examination must not be the mockery which the optional preliminary examination in classics, i. e. the parsing of a dozen lines of Celsus, or Gregory's *Conspiculus*, is at this time at Apothecaries' Hall. This is the veriest mockery that

can be imagined; two in three of the young men who pass it are actually incapable of construing a page of any Latin author on which they have not been expressly crammed. We have ourselves, out of curiosity, examined more than one young man who passed the Latin examination at Apothecaries' Hall *creditably*, and found them alike and utterly ignorant of the Latin tongue,—ingenuous and amiable young men, they owned to as much: how they could have passed was incomprehensible to us, and indeed to themselves it seemed no less so—they *did not know how they had got through*. If the Latin tongue be held necessary, let a knowledge of it be secured; if it be not necessary—as to the general practitioner it certainly is not—let it be dispensed with; a knowledge of the French were a thousand times more useful at this time of day than the Latin.

A preliminary examination, then, on the sciences accessory to medicine, we reiterate, by competent men, appears to us altogether indispensable. Are the present Court of Examiners at Apothecaries' Hall competent? We answer unhesitatingly, and without disparagement to the respectable gentlemen who compose it, that the duty they have to perform is not only beyond their strength, but beyond the strength of any equal number of medical men in the kingdom. These subjects they are required to embrace in their examination are too numerous and vast. Each individual has, therefore, nothing for it but to get up a limited portion of any one, and this circle of short radius he travels over and over again, until he has trodden it bare, and it becomes as distinctly marked out, and as well known to the grinder, as the path from Bridge Street, Blackfriars, to the Strand.

These examiners, again, are mostly men somewhat advanced in years. Age, God knows, is no sin; but it is a

disqualifying circumstance in an examiner upon physical science. Young men can only be well and truly tested as to their diligence and knowledge, in what is called the *science of the profession*. But science is ever progressive, and, alas the day ! when we have passed the middle period of life, we do not advance with her. The general anatomy of the present day, how different from that of Bichat, even from that of Mr. Grainger (1829), and of our contemporary, Dr. Craigie (1831) ! The physiology of 1804, how different from the physiology of 1844 ! Chemistry in her present guise would scarce be recognized as their once-loved mistress by Stahl and Black, Lavoisier and Fourcroy ; even Davy, dead but some half dozen years, would pause before he said she was the same whom he had wooed so ardently, and so triumphantly had won. There is nothing for it then, we believe, but Examining Committees of men between 30 and 50 years of age,—brief interval in the life of man, when the judgment is mature, the experience is ripe, the pursuit of knowledge has scarcely slackened, the thirst for new information has not yet been quenched ! These are the men who, of the day, are still its front and eye, who are ever in advance of aught that the grinder has to give, and who can always make his efforts at cramming nugatory. Why do the young men not grind for the College ? Because the circle upon which they are taken there can be compassed ; and because, as they say, the examination at the College is *fair* ; by which is meant, that there are few or no fancies indulged in for specific answers to specific or preconcerted questions ; that the examiners are, in fact, familiar with the *whole of the subject* upon which they put questions, and can in a moment detect the man who is crammed, from him who has laboured diligently during the term of his pupilage, and who has by

his own application made himself master of the rudiments of his profession. *General proficiency* here is the only test, and ought to be the condition indispensably requisite to carry a man through. But to ascertain general proficiency, is it not obviously necessary that the examiner should himself be proficient ; that he should be intimately acquainted with the entire branch upon which he conducts an examination ? And how shall we hope for proficiency in all branches, among any set of men in the world ; how much less in a committee of men, selected indiscriminately, by seniority or rotation, mostly of limited education originally, and whose tastes and pursuits are often as alien to science as light is to darkness ? Where is the examiner in the Court of Apothecaries' Hall who has advanced botany, or chemistry, or electricity, or medicine, or who has name and fame for his knowledge of any one of these subjects ? on each and all of which he is, nevertheless, required to test the science of candidates for their license. If it be not the somewhat subordinate department of midwifery, there is not a member of it who is known beyond the circle of his own private connections. How different the constitution of the Court of Examiners at the College of Surgeons ! Here we find men of liberal education, who have made for themselves European reputations, who have extended the boundaries of human knowledge, and who have, almost without exception, as heads of great hospitals, had unlimited opportunities of acquiring the art and science of their profession. It is the same at the College of Physicians, where we have known the Court of Examiners constituted by such men as Bright, Chambers, Holland, Paris, and the accomplished Halford. At the College of Surgeons, at this moment, we perceive the examining body numbering

such names as Brodie, Cooper, Guthrie, Lawrence, Travers, and others less widely known to fame only because they have not proclaimed themselves through her approved instrument, the press. It is because there are intellects like these presiding at the College of Surgeons that the examination there is not to be achieved by the degrading process of grinding, with all its evils, antecedent and prospective—idle and vicious habits contracted as antecedents, ignorance and incapacity entailed to the end of life as consequences.

Examinations, however, in all our institutions, want much to render them what they ought to be. If they have any meaning at all, they ought to be felt as a bar insurmountable to incompetency. But are they so? We answer, never. The booby who would not even have made a respectable bricklayer or shoemaker—whose destiny, by nature's fiat, was hod-man, hewer of wood, drawer of water—who would have looked well taking his part at a two-man beetle, and making pavements for the public—is finally let loose upon the world, to become responsible for the limbs and lives of the community; and this upon the score, at length, of—what will our readers imagine?*—the number of times he has been rejected.* "This is very bad!" says the examiner. "It is the third; or it is the fourth time I have been up," whines the dolt. "Well, well, my poor fellow," adds the examiner, "you shall pass this time." And so the seeming strictness of the examination ends. Now the examiner here is no whit more defensible than were the juryman who should lend himself to a verdict contrary to the evidence adduced. *The profession ought to be altogether inaccessible to incompetency.* We trust that the day is not far distant when it will be so. Two or three cases of final rejection—of declared incompetency to become

members of the medical profession—would have a most salutary effect on the whole tone and temper of the medical student's life and habits, and would prove another and a well-directed stab at the vitals of the vile grinding system.

COLLEGE OF SURGEONS,

AND THE COMMITTEE OF THE MEDICAL PROTECTION ASSEMBLY.

[The following address has been sent to us by the Committee, for publication in our Journal:—]

An Address from the Members of the Royal College of Surgeons of England to the Council of that College.

Gentlemen,—In addressing you, at this vitally important juncture, as the governing body of the College of which we are members, we shall not offer to you either the language of remonstrance or complaint; but we feel it to be a duty which we alike owe to the public, to the Crown, to the members of the medical profession, and to ourselves, to remind you of the power which you have authority to exercise under the provisions of the Charter which her gracious majesty granted to our College in the month of September, 1843.

In the *second* section of that royal decree you were empowered to elect, within three months from the date of the sign manual of the Sovereign, not less than two hundred and fifty, nor more than three hundred MEMBERS, who should, from thenceforth, become FELLOWS of our College. In the same section it is also provided that *after* the expiration of three calendar months, and *within one year* from the date of the Charter, "any other persons whom the Council shall *think fit and appoint*, shall be FELLOWS of the College."

We also request your attention to the *fourth* section of the said Charter, which we here present to your notice verbatim:—

"4. That it shall also be lawful for the Council of the said College, at any time or times after the expiration of the said three calendar months, and before the expiration of one year from the date hereof, by diploma or diplomas under the seal of the said College, and in such form as the said Council shall

think fit, and without any fee, to appoint any other person or persons (being a member or members of the said College) to be a Fellow or Fellows of the said Royal College of Surgeons of England."

You have already selected, within the period prescribed by law, the three hundred members of our body, and created them FELLOWS of the College.

On the principles which have guided or regulated your choice in this selection we offer no comment; but we consider it to be our duty to remind you that *additional* creations of FELLOWS have not been announced by you, although *four* months have elapsed since the 14th of December last (when the first three months of your power to elect fellows terminated), and that there remain but five months of the entire term which the Charter has prescribed for the further exercise of your authority. Hence it has become our imperative duty to remind you of the power with which you are invested by the Crown.

The members of our College amount to upwards of ten thousand in number. For ought we know to the contrary, only three hundred of us have, up to this time, been created Fellows by you, under the provisions of the new Charter. This is rather an alarming result of a seven months' exercise of your creative power.

The *Fellows*, be it remembered, are to be the future *electors* of the Council.

The privilege of *election* is a right which we, the members, have endeavoured to obtain from the legislature during nearly twenty years. Instead of conferring it upon *us*, directly, the Crown has invested *you* with full authority to enfranchise *us*. The Crown rightly judged, perhaps, that *you*, who granted us our diplomas, must be better acquainted with our characters and capabilities than could be any body of unprofessional persons with whom we had never been intimately associated.

The fact, in truth, cannot be concealed, that *you* have authority to enfranchise *every member of the College who resides within the limits of this kingdom*. You might even bestow the fellowship on members who live beyond those limits. For the proofs of these allegations we refer to the sections already quoted, in which it is distinctly stated that it shall be lawful for the Council, within twelve months from the

date of the Charter (14th September, 1843), to appoint, without fee, "any other person or persons, being a member or members of the said College, to be a Fellow or Fellows of the said Royal College of Surgeons of England."

These words admit not of two interpretations. They possess an obvious, a perfectly unequivocal meaning. The authority to create *thousands* of Fellows from among the existing members of the College is by law vested *with you*, the Council.

Thus, the power to enfranchise *us*, to bestow upon *us* the right of electing the future Councillors of the College, *now exists with you*. It will *expire* on the 14th of September next. We think, then, that we are justified in demanding at your hands that it shall be exercised promptly, comprehensively, liberally, justly; and we venture to express an anxious hope that the employment of it, by you, will not be tainted either by prejudices or dishonest partialities.

We refer to this new *Charter*, which has invested you with so much authority, as to a highly important sign in the present crises of our affairs. We respectfully remind you that as *you* are now empowered by law to bestow upon *us* the right of enfranchisement, so upon *you* will fall the whole weight, responsibility and disgrace, which would attend an unconstitutional, illiberal, unjust, exercise of the unusual functions with which you have been invested by the Crown. We have the honour to be, Gentlemen, your's, &c. &c.

[There is much in the above address to command attention, everything to secure respect; in taste as well as form it is unexceptionable. We may reasonably expect, before many weeks have passed, to have the whole subject of the medical institutions of the country before us in the bill of the minister, till which time we withhold comment.—ED. GAZ.]

ROYAL MEDICAL & CHIRURGICAL SOCIETY.

WE trust we were not the cause of the somewhat thinner attendance than usual of the Fellows at the very interesting and animated meeting of Tuesday evening last. We are happy to assure the Fellows that they may now venture upon the Society without risk of suffocation; they will, in fact, feel more at their ease than they have done during the whole of the present season.

There was fresh air admitted on Tuesday, the gas lights were judiciously tempered, and though the room did become warm towards the close of the meeting, it never reached the coke-oven point of the preceding evening; the atmosphere never felt disagreeably hot, never in the least oppressive. The consequence was that the Fellows' lungs did their office duly, that the Fellows' brains were adequately supplied with properly decarbonized blood, and that the evening proved one of the most pleasant and instructive which we have ever passed within the walls of the Society.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.

On Monday, the 22d instant, the distribution of prizes among the pupils of St. George's Hospital Medical School, for the Session 1843-44, took place in the theatre, Kinnerton Street. William Pepys, Bart. in the Chair.

Clinical Surgery, by Sir B. Brodie.—Prize, Mr. Thomas H. Smith; Honorary Certificate, Mr. I. Tyrell C. Ross.

Practice of Physic, by Dr. Macleod.—First Prize, Mr. Edward Martin; Second Prize, Mr. F. E. Barton; Honorary Certificate, Mr. J. H. B. Sandon.

Surgery, by Mr. Hawkins.—Prize, Mr. T. H. Smith; Honorary Certificate, Mr. George F. Fletcher.

Materia Medica, by Dr. Nairne.—Prize, Mr. Edward B. Batten; Honorary Certificate, Mr. Edward H. Philippe.

Anatomy, by Mr. Tatum.—Senior Prize, Mr. R. W. Coe; Honorary Certificate, Mr. T. H. Smith. Junior Prize, Mr. William A. Gillow; Honorary Certificate, Mr. J. C. Collins.

Midwifery, by Dr. Lee, who, however, was prevented, by a professional engagement, from attending.—Prize, Mr. Richard F. Freeborn; Honorary Certificates, Mr. T. H. Smith and Mr. F. E. Barton.

Botany, by Dr. Dickson.—Prize, Mr. James George; Honorary Certificate, Mr. James J. Mitchell.

The prizes consisted of useful books handsomely bound.

OLEAGINOUS URINE.

To the Editor of the Medical Gazette.

SIR,

THE reply of Dr. J. W. Griffith to my inquiries in reference to a case of *oleaginous*, not *milky* urine, as it is headed in your number for the 1st of March, even though it is coupled with directions to "read his book," with which I have complied, is not at all satisfactory to me in elucidating the

pathology of the case I narrated, however gratifying my fulfilment of his wishes may be to him. If my memory serves me rightly, the purpose of Dr. Golding Bird's request was to be informed of cases of *oleaginous* or *milky* urine, in order that by the comparison of their several symptoms, &c. some light might be thrown on their pathology; and my object in publishing the case I had met with was, first, to aid Dr. G. B.'s inquiries; and next, to learn where I could meet with figures of the salts of the urine and other animal fluids; for had I been aware of the existence of Dr. Griffith's work, I should have referred to it at once for some of the appearances presented by the salts of the urine, and I should only have mentioned the symptoms of the case, and the concurrence of oily matter with the peculiar saline deposits.

Dr. Griffith's reply, then, is not satisfactory to me, first, because he has left the main pathological question untouched; secondly, because neither he nor "his book" explain the nature of *all* the crystalline forms observed; and lastly, and perhaps not least, because when, avowing my ignorance, I ask for information, I am reproached for inattention to particulars of the importance of which I was not aware. Perhaps, however, I do not "kiss the rod" as I ought, and, like many sinners in graver matters, console myself with the reflection that I sin in very good company; otherwise, Dr. G.'s book, or some other of the kind, would be in the hands of more medical men than I fear it is at present.

Touching my omission of one particular, viz. the colour of the crystals, I mentioned the *redness* of the lithic acid on the sole occasion when I did observe any colour; though, Mr. Editor, thanks to my bad writing, and to your printer's devil, I was made to say *mulberry-shaded* instead of *mulberry-shaped* grains. Next, as to neglect to point out the size of the crystals, my ignorance must be my shield, for I have all my life thought that magnitude has a relation to distance, and as I have no micrometer fitted to my microscope, I fear I must continue to mistake Dr. Griffith's mountain for the mouse that proceeds from it. But if the Doctor wishes to know the power of the object-glass, it was $\frac{1}{16}$ th of Powell's that I used, though the objects were visible by a much lower power.

In excuse for my third neglect—to apply more tests—I beg to state that my search was directed to the organic matters of the urine, and not to its salts; and concluding that I should meet with all the insoluble portions in the sediment, I only reserved a few drops of this for examination, which I placed on a glass slide, testing different portions of it with nitric acid and liq. potassæ.

The same excuse must serve for my inattention to the *quantity* of the oleaginous matter, which was exceedingly small, as it only arrested my attention under the microscope; but as its presence (which I tested with æther) and not its amount, appears to me to be the chief feature of the case, I do not see that Dr. G.'s objection on this score has much weight.

The last blow of Dr. Griffith, and the heaviest of all, because it is weighted by "the best authors," is one aimed at my practice in giving calomel and squills, and saline diuretics, viz. Acet. Ammon., Pot. Tart., and Sp. Æth. Nitr. in albuminuria after scarlatina. But even a worm will writhe, and I would venture to remind Dr. Griffith that if he be as well acquainted with the *practice* of medicine as he is with some of its collateral branches, he must know that the very best theories of the nature of a disease are frequently very unsafe guides in the treatment of it. Of this truth I would refer him for many melancholy examples, to the hyper-theoretic practice of our Gallic neighbours, who have not long learned that purgatives may be safely given in gastro-enterite, and have been sitting lately in solemn conclave, in their Academy of Sciences, to hear the question discussed, whether opium, in *any* form, may be used in inflammatory diseases. In my case there appeared to me to be more danger from congestion of the lungs than of the kidneys; and as the weakness of the patient precluded the abstraction of blood, I gave him calomel to affect his mouth, and thus check the inflammatory symptoms, at the same time that the squills would promote expectoration, and assist the action of the diuretics.

In a very protracted case of albuminuria after scarlatina that I attended some time back, in which there was threatening of hydrocephalus, and which I had treated according to the "best authors" in vain, I found Quinine and Sulph. Acid effect a speedy cure, my theory being, that the albuminuria, which had begun in irritation, was kept up by the debility of the vessels, which state quinine would probably cure, as, indeed, it very quickly did. In short, if I cure my patients, *cito, tuto, et jucundi*, it matters little to me whether I act in accordance with the views of the "best authors," or those of one who is nullius addictus jurare in verba magistri.

I am, sir,

Your obedient servant,

T. OGIER WARD, M.D. Oxon.

21, Lower Phillimore Place, Kensington,
April 18, 1844.

P.S. The spiculated crystals which I observed were lithate of ammonia, (Plate I. fig. 3, of Dr. G.'s "book"), not lithate of soda, as Dr. Griffith supposes; but I can-

not say whether the sword-shaped forms were chloride of sodium modified by urea, or the bibasic phosphates; but I suppose the former, as they were, in several instances, so varied in their shape as to resemble the last form in Plate II., fig. 30, op. cit. except that the arms of the cross were more circular than oval, like the crenated outline that would be presented by four, five, or six equal circles meeting together in contact, or like Gothic trefoils, quadrefoils, and cinquefoils.

ON THE GASTRIC JUICE,

AND ITS INFLUENCE IN NUTRITION.

BY M. CLAUDE BERNARD.

THE general tendency of the researches of modern chemists and chemical physiologists has been to reduce the action of the gastric juice to that of a simple solvent of the solid articles of food. Fluid articles of aliment have been held independent of its action; they can make their way into the blood, in virtue of their fluidity; and having done so, they were believed competent to serve all the purposes of nutriment in the animal economy. The experiments of M. Bernard are both interesting and important, inasmuch as they go far to demonstrate that these conclusions are premature; that the gastric juice does more than merely reduce solid articles of aliment to the liquid state and so fit them to enter the circulation, and that liquid aliment, admitted to be of the most nutritious kind, is so only after it has undergone the action of the gastric juice; gum, sugar, albumen, &c. introduced directly into the circulating system, are not retained and used by the living being for its various purposes, but are forthwith separated and thrown out as foreign to its nature, and incapable of ministering to its wants.

The gastric juice is admitted on all hands to be an acid liquor; but its acid has been variously stated to be the acetic, the hydrochloric, the lactic, the phosphoric. The latest analysis of the fluid which we possess, is that of M. Blondlot, according to whom it consists of water 99 parts, salts and organic matter 1 part, the salts consisting of superphosphate of lime, phosphate of ammonia and chloride of sodium, the organic matter of certain aromatic principles, mucus, and a particular matter (pepsine or gastrosé?). [The acid according to this account would therefore appear to be the phosphoric; but it seems highly probable that the lactic acid which is notoriously produced in such quantity from the food during the act of digestion, contributes essentially to the solution that is effected: a large quantity of acid is required in this process, a very small quantity of pepsine suffices; nature, sparing in causes, fertile in effects, takes advantage of

what may be held an accident—if there be such a thing in the economy of the universe—to accomplish one of her important laws: a little pepsine is added to the food become acescent in consequence of the moisture and temperature to which it is exposed in the stomach, and it is forthwith dissolved and fitted for assimilation. Ed. M.G.] The mucous membrane of the stomach appears, however, to have a positive faculty of separating acids from the mass of the blood. Solutions of the lactic, phosphoric, butyric, and acetic acids, thrown into the veins of a living animal, are by and by discovered in the stomach; their salts, again, as the tartrate of iron, the butyrate of iron or of magnesia, &c. injected into the veins, are decomposed; their acids appear in the secretion of the stomach, their bases show themselves in the urine. Mineral salts, finally, which are not susceptible of decomposition in the blood, pass unaltered into the gastric juice. It may therefore be assumed as a general thesis, that the mucous membrane of the stomach, in producing the gastric juice, only separates acid principles from the blood which this fluid contains already formed.

To show that the combination of alimentary matters with the gastric juice is an indispensable condition to their becoming true nutriment, these experiments were performed:—

Four healthy dogs had each rather more than half an ounce of distilled water (twenty grammes) mixed with rather more than half a drachm (five gram) of fresh white of egg thrown into the external jugular vein. The urine examined before was not found to contain any albumen; after the experiment it was discovered in every instance to contain this substance. Other four healthy dogs had the same quantity of albumen, raw or boiled, but previously digested in 20 grammes of gastric juice for twelve hours in the water bath at from 100° to 104° F. injected into their jugulars; in no case could the slightest trace of albumen be discovered in the urine either by heat or nitric acid. In like manner two and a half drachms of sugar dissolved in about six drachms of water were thrown into the jugulars of three dogs. The substance was found in the urine unchanged; cane sugar as cane sugar, grape sugar as grape sugar. After an interval of three days, the same quantity of cane sugar which had been previously digested in gastric juice at a temperature of about 104° F. for six hours, was injected into the jugulars of the same animals. In this instance, the urine, carefully analysed, did not yield a trace of sugar.

It is certain, therefore—1st, that sugar and albumen, not previously subjected to the action of gastric juice, are eliminated from the blood unchanged by the kidney; 2dly, that sugar and albumen artificially

chymified, i. e. digested for a certain time at a suitable temperature in gastric juice, are retained in the blood, and are there decomposed; they are not eliminated until they have undergone combustion, for which they are prepared or fitted by the peculiar molecular action of the gastric juice.—*Gaz. Méd. de Paris*, March 16, 1844.

CULTURE OF THE SUGAR CANE,

AND PRODUCTION OF SUGAR.

SUGAR, as an important article of diet, seems to come fairly within our province as medical journalists. M. Casaseca, of the Havana, has just communicated some interesting observations to the Royal Academy of Sciences of Paris, on the chemical composition of the cane that is cultivated around that city. It is a very remarkable fact that, until the year 1839, science was still without any reasonably good analysis of the sugar-cane, when one, extremely satisfactory in all respects, was made public by M. Peligot. It can only be ignorance of the results of M. Peligot's researches that leaves the manufacture of sugar in its pristine state of rudeness and relative unproductiveness. In the British West-India colonies, if a pan, duly concentrated by boiling, produce 26 cwt. of concrete matter, it is thought very well if from this mass 12, 14, at most 16 cwts. of cured sugar are obtained; the other 10 cwts. have flowed out in the shape of molasses. Now *the whole of this molasses*, which, at the present market price of rum, is almost valueless, *has been produced at the expense of the same, or a somewhat greater, weight of perfectly crystallizable sugar.* In the juice of the sugar-cane there are not two forms of saccharine matter, one crystallizable, the other syrupy, as is commonly supposed, it, in fact, *contains no treacle*—nothing but pure sugar, a few salts, a little albumen, and water; and M. Peligot computed that the juice which usually yielded no more than from 6 to 10 per cent. of muscovado sugar, contained in reality from 18 to 19 per cent! If this be so, there is an actual destruction of sugar in the manufacture, of from one-half to two-thirds!

These conclusions have all been borne out, and more than borne out, by the researches of M. Casaseca, who, from a portion of sap as it ran from the crushing mill, obtained these quantities:—

Crystallized sugar	20·94
Water	78·80
Salts	0·14
Organic matters other than sugar . .	0·12

100·00

Here is consequently very nearly 21 per cent. of crystalline sugar, and not a drop of molasses.

It would appear that the variety of cane that is cultivated is by no means a matter of indifference. M. Peligot, from his analysis of the Otaheite cane, estimated the quantity of woody fibre at about 10 per cent. The canna de la tierra of Havannah, M. Casaseca found, on the contrary, to contain as much as 16·4 per cent. of woody fibre. In trying different canes, M. Casaseca found that from 100 of the *crystalline* cane he obtained 65·0 of trash; from the same quantity of the *ribbon* cane, 55 of trash; and from the like quantity of the *Otaheite* cane, no more than 43·5 of trash. If the object of the colonist be to grow *timber* therefore, he will cultivate the canna de la tierra; if he would have sweet sugar-yielding *sap*, he ought to look after the Otaheite cane. If he would make marketable sugar, rather than valueless molasses, he will give up boiling in an open teache, and send forthwith to England for a vacuum pan. His additional profits the first year, if he be a producer to any extent, will more than pay the expense.—*Comptes Rendus*, No. 10; and *Editor Med. Gaz.*

INJURY OF THE OMENTUM— DEATH.

A HUSSAR felt, as he said, a "crack in the breast," as his horse came to the ground after taking a leap. Next day he complained of pain under the short ribs of the left side; he had cough, with bloody expectoration, and swelling as well as pain of the left hypochondrium. The bowels were obstinately confined; the urine scanty and high-coloured; the pulse very small and rapid. Things went on from bad to worse, and the patient died early next morning. On examining the body, a rent in the omentum, to the left side, and one inch and a half long, together with five ounces of bloody effusion within the cavity of the abdomen, were discovered. The lungs appeared quite healthy.—*Dr. Derner, in Casper's Wöchenschrift*, No. 4, 1844.

THE SHADE AND THE SUN.

AT Naples there is a popular proverb, accredited like an article of religious faith, viz. that all diseases come in the shade and are cured in the sun. The porter of the mole, when weary and exhausted, throws himself down, sleeps an hour or two in the sun, and rises again revived and strong; the fisherman, feeling the effects of exposure to the moist air of the night, chilled and indisposed, lays himself in the sun, falls asleep, gets into a hot bath of perspiration, and is well again. The inhabitants of all grades, the aristocracy especially, live as near as possible to the flat roofs of their houses, where they sit for hours, exposed to the full glare of their scorching sun, in a dreamy daze, looking out upon their beautiful bay.

The sun, in short, is their panacea, their *Æsculapius*.—*Carrière, in Gaz. Med. de Paris*, No. 14.

Medicine and the Collateral Sciences.

FRIDAY, MAY 3, 1844.

MORAL TREATMENT OF INSANITY
IN BETHLEM HOSPITAL.

To the Editor of the Medical Gazette.

SIR,

THE recent publication of a Report on the Royal Hospitals of Bridewell and Bethlem*, the first that has ever appeared through the long succession of centuries during which these establishments have existed, affords me the grateful opportunity of making a few observations, and of presenting you with an abstract of the publication for insertion in your excellent journal.—I am, sir,

Your obedient servant,
R. WILLIS.

Dover Street, April 8, 1844.

I make bold to avow my want of knowledge of the original cause which led to the conjunction under one board of governors of a house for the correction of criminals, and a house for the treatment of sickness. The prison may possibly have been a graft upon the hospital; or the union may be an evidence of those barbarous times when the sad visitation of insanity was looked on as a crime, when the hapless insane were dealt with as criminals. These times have passed; and I confess I should like to see an amicable separation between Bridewell and Bethlem Hospital.

As practitioners of medicine, we are of course rather interested in the hospital than the prison portion of the Report; and it is to this that I desire to call your readers' attention.

Among all the directions in which medical science has made mankind her debtor,—and they are vastly more numerous and far spread than appears to the superficial in-

quirer,—there is none more worthy of being dwelt on than that which has the treatment of insanity for its object; none in which the genius of the healing art, leading Humanity in either hand, has had more signal triumphs to boast than here. The ample proof of this is stamped upon the pages of this excellent Report, from the perusal of which all must rise more deeply impressed than ever with the feeling that the office of physician is one truly holy, and that the service rendered of old in special temples to the Divinity conceived in one of his noblest attributes, is not yet extinct on earth, but has a true priest in every worthy member of the medical profession.

From the Report, we learn that in the course of the year 1843, 284 patients—109 males, 175 females—were admitted into the Royal Hospital of Bethlem, and that the relative number of cures, progressively on the increase, has been greater in this than in any preceding year: it is as high as 56 per cent. upon the admissions. The advantages of providing employment for the patients has been strongly perceived, and doubtless some considerable share of the greater success of the remedial measures employed must be ascribed to this cause. Besides the ordinary and incidental occupations, such as gardening, white-washing, painting, cleaning the wards, &c. a range of workshops has been added as a means of affording constant and regular occupation to the patients. "The only argument," says the Report, "that can be used against granting employment is, that great risk is incurred in allowing patients the use of dangerous instruments necessary in the manufacture of the articles on which they are employed. This argument would go to the prohibition of all employment whatever, and the deprivation of every article by which injury could be inflicted by the patients, either upon each other, or their attendants. But when it has been found that patients may be safely trusted in the gardens with hoes and spades, in the car-

* General Report of the Royal Hospitals of Bridewell and Bethlem, and of the House of Occupations, for the Year ending 31st December, 1843.

penyer's shop with all the implements of that trade, with sledge hammers and rods of iron in the forge, with brooms for sweeping the wards, &c. and that no accident of the most trifling character has occurred, but that, on the contrary, the habits of the patients have been most materially benefited by their gradual restoration to their ordinary occupations, and by attracting their attention to new methods of employment, it may be fairly inferred that the several trades which it is proposed to establish may be carried on, under proper superintendence, not only without increased danger, but with still more extended advantages." It is impossible to doubt but it will.

"On the female side, again, the excellent matron, Mrs. Hunter, to the old list of occupations, has added straw-plaiting, bonnet-making, shirt-making, lacc-making, and fancy work, and with the best effect. The cheerful and spacious apartment recently completed and furnished as a work-room, affords abundant evidence of the industry of the inmates, and of the skill of the superintendent. Not long ago one of the patients presented a pair of very handsome slippers, made entirely by herself, to a noble Earl, whose constant attendance and unwearied attention to the best interests of the Hospital are not more honourable to himself than beneficial to the establishment. Gratified by the pleasure which this present occasioned, she requested permission of another Governor to be allowed to work a pair for him, in return, she said, 'for his kindness and attention to the patients.' It may appear superfluous or unimportant to mention circumstances of this nature; but when it is recollected that a lunatic asylum was once but another name for all that was painful and degrading,—when, even now, it is difficult not to associate with it ideas of sorrow and suffering, of harshness, and perhaps of cruelty,—it is pleasing to be able to record these simple traits."

It is a kind heart and a sound head that guides the pen in such language as this; and the noble Earl in the poor mad-woman's slippers received a badge more truly honourable to him as a man than had he won the Garter and the Cross of St. George in the cabinet or the field!

Considerable additions have been made to the amusements of the patients on both sides of the Hospital. "On the male side a library is in the course of formation, and contains a selection of useful and entertaining works, which have been under the charge of a patient as librarian. Chess, draughts, cards, and backgammon, have long been allowed with very beneficial effects. On the female side a pianoforte has been purchased, which is a source of great gratification, not only to those who are able to play, but to

the other patients. On the evening of the last Saturday of the year, nearly thirty of the female patients were assembled to celebrate the festive period, and nothing could exceed the order which prevailed, and the pleasure which was then communicated. One of the Governors happening to visit the work-room with the matron on the following Monday, received a full account of the little entertainment from the patients, and was requested to convey to the Governors the expression of their gratitude for this attention to their comforts."

Who shall say now that the minds of the insane are dead, are not alive to many of the best feelings of our nature? A single instance of the beneficial effects of these amusements as remedial means may be mentioned.

"A patient who was brought to the Hospital in a state of extreme violence, on being released from the strait waistcoat in which he was confined, immediately knocked down three attendants, and was with great difficulty placed in his apartment. The next day, although labouring under very great excitement, he was taken into the amusement room; and the effect was very striking. He appeared astonished at seeing a number of persons engaged in reading, at cards, and draughts, and playing at bagatelle; he became calm, joined in the amusements going on, remained a quiet and tractable patient, and was discharged cured while the Report was going through the press."

It was in Bethlem Hospital that the example was set in this country of liberating lunatics from personal restraint, and it is gratifying to see that the restraint system is on the decrease. In 1840, the weekly average number of patients under restraint was $13\frac{1}{2}$; in 1841, it was 9; and in 1842 and 1843, no more than about 3. The attendants, no longer called *keepers*, which connected their office with that of the gaoler, are aroused to increased vigilance by the necessity of closer attention; and living with and among the patients, gradually acquire their confidence, and become the directors of their occupations, and the companions of their amusements. Insane patients are perhaps even peculiarly alive to the painful idea of confinement and coercion; everything like a parade of locks and bolts, and even of ordinary precautions, which tended to irritate the feelings and destroy the confidence that is found so beneficial between the patients and their guardians, have, therefore, been withdrawn, with the best effect; the wages of the attendants have been raised, their comforts carefully considered, and a class of men as different from the old keepers secured as it is possible to conceive. Nor is everything left to the sense of duty of the attendant: the galleries have all been furnished with night-clocks or tell-tales, by which neglect on the

part of the nurse or attendant in making the round at the proper hours is certainly made known.

Bathing used to be ranked among the medicinal means, and was only used when specially directed by the physicians; but by the new regulations every patient has now a tepid bath once a week, unless forbidden by the physician, and each patient has farther two changes of body linen in the course of the week, instead of one, as formerly. The old hospital uniform dress has been abandoned; instead of bone implements, convalescents, and many others, have now metal knives and forks at their meals, and earthenware plates, instead of the wooden platters and bowls formerly in use. The bedding, too, has been improved, horse hair and wool-mattresses having been ordered, wherever they can be advantageously substituted for the old straw sack. Tea and coffee, with sugar—to which the majority of the patients had been accustomed all their lives—now form part of the ordinary dietary of the hospital, and are felt to be an immense addition. This change, however, has of itself entailed an additional charge on the Hospital of nearly £400 per annum. Sorely and peculiarly as the income tax presses upon medical men, I believe that we should all grant it joyfully to the minister, would he but get over the barbarism of regarding items in the necessary and daily food of the community as articles of luxury, and cease to make them sources of revenue to the exchequer. The sum of £400 would be reduced to £200, were there no discriminating duty upon sugar, and no absurdly high impost upon tea.

The necessity of seeking early for advice in cases of insanity is well known to the profession, and its advantages are illustrated in the Report in the best of all ways—an appeal to the success of the remedial treatment at different periods of the disorder. The chance of recovery is in exact proportion to the shortness of time during which the disease has existed; the probability of effecting a cure of the patient who is received within one month is generally just double that of restoring one who is received within two months from the commencement of the attack. So short an interval as thirty days lessens a man's chance for restoration to himself and society by exactly one half; if he had two chances in the first instance, he has but one in the second. From the Table No. 8, we see that of the entire number of 284 patients, 106 were received within one month; but between one and three months the number is still greater, viz. 108. The great relative disproportion of cures effected in males and females is somewhat startling. Whilst 103 of the 175 female patients are discharged cured within the year; of the

109 male patients, no more than 56 are so discharged. I do not observe this circumstance commented on in the Report, and beg to call the attention of the Governors and Medical Officers particularly to the fact. There is a cause for it, which being inquired into will be discovered, and which, if remediable, will be redressed; if irremediable, it will be known, and knowledge is always light from heaven. The total proportion of cures, and the general sanatory state of the hospital, however, it is most gratifying to observe, have gone on steadily improving. In the middle of the last century, the cures amounted to no more than 33·20 per cent. annually, and the ratio of deaths was as high as 25·43. Last year (1843) the ratio of recoveries reached 56 per cent. and the deaths were only 5·93—say 6 per cent. How soundly the heads should sleep that have been instrumental in bringing about such glorious results! And as a regiment depends for its efficiency on its colonel, adjutant, and doctor, so let me state that an hospital, for its efficiency, depends on its matron, steward, and medical staff, that I may find an opportunity of mentioning the names in connection with the facts above given of Mrs. Hunter and Mr. Nicholls—the intelligent matron, the old and faithful steward.

There is yet another point alluded to in the Report, to which I shall direct attention; it is the admission of pupils to the Wards of Bethlem Hospital, as a school where they may acquire a competent knowledge of the paramount disease of the brain and nervous system—insanity. “The Court,” says the Report, “could have conferred no greater boon upon society, than by giving every facility to medical pupils for acquiring a knowledge of this distressing affliction, and of the best methods of treatment.” The fee payable to the medical officers by each pupil used to be fifty guineas; it has lately been reduced to twenty guineas for one year, or fifteen guineas for six months. I ought not to advocate, I do not advocate, any curtailment of the poor reward in money which medical men derive from their onerous duties as physicians and surgeons to public hospitals; but twenty, or even fifteen guineas, is far too large a sum—so large that it will render the opportunity now afforded nugatory. I am myself so hostile to the division of the several grades of our profession into mad-doctors, lung-doctors, stomach-doctors, oculists, orthopedists, &c. &c. that I fondly hope the existence of the mad-doctor will one day become matter of history. Restriction or limitation is always injurious to general efficiency, and all true improvement in the treatment of insanity, as in every thing else in medicine, has come from the general physician. Dr. Philip Pinel, the grand reformer in the

department of insanity, practised generally; Dr. Conolly spent most of the best years of his life in general practice as a physician; and the wards of Bethlem have been thrown open to the rising generation of medical men by the active enterprise of a general physician, Dr. Webster, to whom, in conjunction with Mr. Laurie, the world is indebted for the admirable Report which has interested me so much.

Thanking these gentlemen very heartily for the instruction which they have afforded me, and referring your readers to the Report itself for much valuable information, I conclude by wishing the authors life and leisure to write many more annual reports of Bethlem Hospital, such as this which they have now published.

CASE OF
INFLAMMATION AND GANGRE-
NOUS ABSCESS OF THE LUNGS,
FOLLOWING A STATE OF PARTIAL ASPHYXIA
PRODUCED BY A POISONOUS DOSE OF
OPIUM.

BY J. D. HEATON,
(*For the London Medical Gazette.*)

MARY MACCARTHY, aged 28, admitted to the hospital of University College, under Dr. Williams, May 1st, 1843. A large, strong-looking woman, with a florid complexion.

Four months ago, on account of some pecuniary distress, she swallowed nearly a wine-glassful of laudanum, with the intention of poisoning herself; she immediately afterwards vomited freely, and experienced little ill effect from the poison.

About a month ago, she again took nearly two ounces of laudanum; this she did not vomit, and she was brought to the hospital the following morning, suffering under the effects of opium. By the use of the stomach-pump, the contents of the stomach were evacuated; and the various means used subsequently, aroused her from the stupefaction into which she had fallen. In a few days, however, symptoms of pneumonia appeared in the right lung, for which she was treated by Dr. Thomson, whose patient she then was. A week afterwards, at her own request, she left the hospital,—the inflammation still existing,—and returned to her own dwelling, in a damp confined situation. At this time, she had a frequent, troublesome cough, and much pain in the right side of the chest; the expectoration had a dirty green colour, and

both this and the breath were extremely fetid. As these symptoms continued, and she found herself getting weaker, and her general health still more declining, she returned to the hospital, and was admitted under Dr. Williams, on the 1st of May, as above mentioned.

Between the time of her discharge and her re-admission, she had noticed the extremely fetid odour of the sputa expectorated by coughing; she also expectorated some dark green shreds of a solid substance, very fetid, and apparently, from her description, gangrenous portions of lung.

The following were the symptoms at the time of her admission: pain and tenderness in the right side of the chest; shortness of breath, and a copious expectoration of a greenish, rather viscid and purilaginous matter, of a fetid smell; great prostration of strength, progressive emaciation; considerable thirst; skin moist; pulse 80, rather feeble; urine natural. Dulness of stroke-sound, and increased vocal resonance on the *right* side of the chest, the breath sound remaining audible anteriorly; near the axilla, the breath sound was loud and tubular, almost cavernous; some crepitation posteriorly. On the *left* side, the respiratory sound was very distinct, almost puerile; posteriorly, there was dulness of stroke-sound, and increased vocal resonance, but without loss of the respiratory murmur.

℞ Tr. Camph. Co. ʒj. ; Acid. Nitric. Dil. ℥x. ; Acid. Hydrochloric. ℥iij. ; Decoct. Senegæ, ʒjss. M. ft. haust. quart. horis sumendus.

Omni mane sumat haust. Sennæ.

Latiri dextro admoveatur Emplast. Cantharid.

May 4th.—Some improvement; cough troublesome; the pain in the chest diminished, but she is unable to procure any sleep.

Horâ somni sumat Morph. Hydrochloric. gr. ss.

6th.—The patient seems more feeble, and the pulse is weaker and more frequent; she continues very restless. There is increased dulness in the lower part of the right lung, and more crepitation.

Adde Haustui quinae disulph. grs. ij. ; lateri dextro applicentur hirudines x.

8th.—There is increasing debility,

and much restlessness; pulse 86, feeble, rather sharp; cough very troublesome; expectoration very fetid, and more purulent.

Ordered to have beef-tea daily, and three ounces of red wine.

On the 10th, the sinking state of the patient seemed to require that the allowance of wine should be doubled.

On the 11th, she seemed considerably better, having passed a quieter night; the feet and rest of the surface were comfortably warm; cough troublesome; pulse 108, still very feeble.

On the 15th, an unnatural puffiness of the surface was observed over the ribs above the right mamma; the respiratory sound here was loud and tubular. The patient complained of much pain in the right axilla on coughing, or taking a full inspiration; probably from some pleuritic inflammation in this situation.

About this time the dose of quinine was increased to four grains, and a little creasote added to the draught, to correct the savor of the breath and expectoration. A nourishing diet was still allowed, varied occasionally to suit her inclination.

On the 20th, there was considerable tenderness over the right mammary region, in which situation the stroke-sound was very resonant, as from emphysema or pneumo-thorax.

At this period, and subsequently, there was evidently increasing debility and emaciation, though without any rapid change from day to day; the pulse gradually became more frequent and feeble. Profuse perspirations, frequently occurring, added to her exhaustion. The frequent cough gave her much distress, and the expectoration continued copious, usually thin and watery, containing dark-coloured flocculent masses.

On the 27th, the stroke-sound in the right back was found perfectly dull; the left back resonant; cavernous rhonchus under the right axilla. The debility was gradually increasing; but otherwise no great change in the symptoms. One day she suffered much from nausea, and vomited a considerable quantity of fluid containing much yellow bile.

On the 2d of June a diarrhoea commenced, which was very troublesome; the perspirations continuing extremely copious. She was reduced to a state

of extreme prostration, and was evidently near her death. The respiration short and hurried; the cough very troublesome; the expectoration quite arrested. She died on the 4th.

Inspectio cadaveris, post mortem horas xxiv.—The body much emaciated. No distortion of the chest.

Thorax.—It was attempted to ascertain if any air was contained in the cavity of the pleura, so as to account for the tympanitic character of the stroke-sound over the right chest, but this was not very clearly made out. The left lung was adherent to the walls of the chest by numerous recent pleuritic effusions readily torn through. The upper lobe of this lung had an irregular puckered appearance, resulting from tubercular consolidations of a dark grey colour; at one point, a small cavity was found, evidently of a tubercular origin, though now in progress of cure, containing only some pale cretaceous matter, the lung around being indurated and containing numerous miliary granulations. The lower and posterior parts of the lung were of a dark colour, and much consolidated, in some parts approaching the appearance of inflammatory hepatization; other parts still crepitating when compressed. The tissue generally was not much softened, but in the interior was found a small cavity rather larger than an almond, having irregular walls, of a dark colour, formed by the pulmonary tissue in a softened and apparently gangrenous state, and containing a small quantity of purulent lymph of a bad odour. In the *right lung*, the two layers of the pleura were united anteriorly by recent adhesions; the superficial colour was of a pale leaden hue, very different to that of the opposite lung. Posteriorly the lung was strongly attached to the walls by old adhesions, and in attempting to separate these, the substance of the lung gave way, disclosing a large cavity from which escaped a gush of purulent and venous matter, (not less than four or five ounces) of an extremely offensive smell. Besides this fluid, the cavity contained a mass of dark gangrenous matter, evidently part of the pulmonary tissue; the walls of this excavation, which extended through a great part of the upper and middle lobes, presented a similar sloughy appearance to the separate mass it con-

tained within. Around this were numerous small cavities communicating with it. The lower lobe of the lung presented a deep red appearance, similar to that of the opposite side. At that point posteriorly where the lung adhered so firmly to the walls of the chest, the internal muscles had a pale flabby appearance, and the serous lining was completely destroyed. The heart was free from disease.

The abdominal viscera presented no unusual appearance.

The interest of this case depends on the good illustration which it affords of the pathological fact that a continued state of partial asphyxia, from whatever cause, even though the immediate effects may be removed, produces such a state of congestion of the pulmonary vessels as may lead to very serious inflammation of the lungs. In the present instance, the asphyxia arose from the stupifying effects of a poisonous dose of opium, under which influence the respiratory movements were so far arrested as to produce for some time a state bordering upon asphyxia. Without going into any detail as to the theory of asphyxia, it will be sufficiently clear that when the movements of the lungs cease to be efficiently carried on, the black blood supplied to them fails to become duly aerated, and finds an increasing difficulty in making its way through these organs, and that this difficulty is increased by the feeble action of the heart, through whose nutrient vessels unoxygenated blood now circulates.

The effect of partial asphyxia in producing this state of the lungs is well illustrated by the old experiment of dividing the par vagum in a living animal. When this operation is performed, respiration ceases to be carried on as a reflex action, and the respiratory movements become entirely dependent on volition. Hence these motions are imperfectly effected. They are, however, still carried on, so far as regards the *evident* motions of the chest, though incompletely and laboriously; but there are, probably, other motions of the lungs, of a more intrinsic nature, not at all under the influence of volition, and effected exclusively as a reflex action; these are the contractions and dilatations of the bronchial tubes which the experiments of Dr. Williams, (during the summer of 1840, and which

were laid before the meeting of the British Association) sufficiently proved to be contractile, and which probably take place in connection with those of the whole chest. This motion of the tubes, together with similar motions of the larynx equally involuntary, must be cut off when the par vagum is divided or paralysed, and this must prove an additional impediment to the respiratory function. The result of this is, that after death the lungs of the animal experimented on are found in a highly engorged state.

The paralyzing effect of opium on the nerves produces a similar result; but, in this latter case, the voluntary movements are impeded, as well as the involuntary. Asphyxiating gases, and various other causes producing this state in a degree not immediately fatal, if continued in operation long enough to deprive the distended vessels of their tonic contraction, produce congestion of the pulmonary plexus. When recovery from the state of asphyxia is effected, the heart regains its full powers, and by its reaction upon the congested vessels, the congestion is converted into inflammation.

The effect of the more ordinary causes of pneumonia is very similar to this of asphyxia; congestion is first produced, which is converted into inflammation. The continued exposure of the surface to cold, constricts the external vessels, and drives the blood upon the internal organs; if any previous weakness or disease exists in the lungs, such as a deposit of tubercular matter, this organ becomes the seat of the congestion so produced, which the reaction of the heart converts into inflammation.

It is seldom, however, that the pneumonia, arising from asphyxiating causes, presents the characters of acute inflammation. The blood may have become so far stagnated in some parts that reaction cannot be produced, and congestion passes immediately into gangrene. Gangrene is by no means an ordinary termination to inflammation of the lungs. It was the opinion of Laennec that when this organ presents the appearances both of inflammation and of gangrene, it is the latter state which precedes and causes the former. This is now considered to be only occasionally, and not invariably the case. But those instances in which gangrene

results from asphyxiating causes are just those in which this state is most likely to precede, and, by its irritating effects, to give rise to the inflammation in adjacent parts. Chomel has related cases in which gangrene of the lungs has resulted from exposure to asphyxiating gases, in which he supposes that the first or congestive stage of pneumonia has passed immediately into gangrene. It appears not improbable that such was the case in the present instance, for the symptoms were at no time those of *acute* inflammation, which is that form most likely to *terminate* in gangrene. Neither was there any attempt set up to circumscribe the disease; the walls of the cavity were themselves in a state of *sphacelus*, presenting no definite boundary. The loose tissue of the lungs is not favourable to such a limitation, and the low character of the vascular action was likewise opposed to the effusion of good lymph requisite to this process. The extremities of the vessels leading to the gangrenous part were, however, closed, as was ascertained by examination, and proved by the circumstance that no hæmorrhage took place. The softened, almost purulent state of the muscular walls of the chest at one point, posteriorly, seemed as though an effort were then making to form an opening externally, for the discharge of the pulmonary abscess.

Besides these changes in the lungs, there was a considerable amount of tubercular disease, both of old standing, and in the form of miliary granulations of a recent date. The tuberculous affection, however, was of a slow and chronic character, and such as might not have seriously interfered with health for many years, though it may have served to aggravate the more acute affection hitherto considered.

The physical examinations during life afforded no very satisfactory signs of the amount of disease which existed within. The dulness of stroke-sound on each side, combined with the increased vocal resonance, showed that there was some unnatural condensation of the pulmonary tissue in both lungs; the crepitation heard in the lower part of the right lung, showed that, here at least, this state was connected with an inflammatory action, and the foetid odour and other characters of the sputa showed that this coexisted with gan-

grene of some portion. But no signs were obtained conclusive as to the existence of a larger cavity in the right lung. The nature of the circumstances, however, satisfactorily accounted for the absence of these signs. In an ordinary tubercular excavation, so long as it remains completely closed and unconnected with a bronchial tube, by which air may be admitted to the interior, no satisfactory physical signs of its formation are afforded; dulness of stroke-sound alone is produced, which may result from condensation alone. Such was the state of the cavity under consideration; it was filled with fluid, which can have had no free communication with the bronchial tubes, otherwise it would have been discharged; and thus, the conditions requisite for the production of pectoriloquy and gurgling respiration, the usual physical signs of an excavation in the lung, were both absent. As some respiratory murmur was heard anteriorly, over the seat of the abscess, some portion of permeable lung must have intervened between this and the front walls of the chest; but the unusual tympanitic character of the stroke-sound observed in this situation, for some days before death, can only be accounted for on the supposition of some pneumothorax here, for the tissue of the lung did not present the appearances of emphysema.

The plan of treatment adopted in this case was locally antiphlogistic, combined with generally tonic and stimulant medicines, and regimen to support the strength, and enable the system, if possible, to throw off the putrid matter contained within the lung. But the symptoms were unfavourable from the beginning; and the extensive disease disclosed after death sufficiently accounts for the fatal result.

REMARKS ON INFLAMMATION.

To the Editor of the Medical Gazette.

SIR,

I HAVE abstained during the last two weeks from sending you any additional remarks upon the doctrines of inflammation as propounded in Dr. Copland's Dictionary of Practical Medicine, in order that he might have an opportunity of answering the arguments which I have advanced in refutation

tained within. Around this were numerous small cavities communicating with it. The lower lobe of the lung presented a deep red appearance, similar to that of the opposite side. At that point posteriorly where the lung adhered so firmly to the walls of the chest, the internal muscles had a pale flabby appearance, and the serous lining was completely destroyed. The heart was free from disease.

The abdominal viscera presented no unusual appearance.

The interest of this case depends on the good illustration which it affords of the pathological fact that a continued state of partial asphyxia, from whatever cause, even though the immediate effects may be removed, produces such a state of congestion of the pulmonary vessels as may lead to very serious inflammation of the lungs. In the present instance, the asphyxia arose from the stupifying effects of a poisonous dose of opium, under which influence the respiratory movements were so far arrested as to produce for some time a state bordering upon asphyxia. Without going into any detail as to the theory of asphyxia, it will be sufficiently clear that when the movements of the lungs cease to be efficiently carried on, the black blood supplied to them fails to become duly aerated, and finds an increasing difficulty in making its way through these organs, and that this difficulty is increased by the feeble action of the heart, through whose nutrient vessels unoxygenated blood now circulates.

The effect of partial asphyxia in producing this state of the lungs is well illustrated by the old experiment of dividing the par vagum in a living animal. When this operation is performed, respiration ceases to be carried on as a reflex action, and the respiratory movements become entirely dependent on volition. Hence these motions are imperfectly effected. They are, however, still carried on, so far as regards the *evident* motions of the chest, though incompletely and laboriously; but there are, probably, other motions of the lungs, of a more intrinsic nature, not at all under the influence of volition, and effected exclusively as a reflex action; these are the contractions and dilatations of the bronchial tubes which the experiments of Dr. Williams, during the summer of 1840, and which

were laid before the meeting of the British Association) sufficiently proved to be contractile, and which probably take place in connection with those of the whole chest. This motion of the tubes, together with similar motions of the larynx equally involuntary, must be cut off when the par vagum is divided or paralysed, and this must prove an additional impediment to the respiratory function. The result of this is, that after death the lungs of the animal experimented on are found in a highly engorged state.

The paralyzing effect of opium on the nerves produces a similar result; but, in this latter case, the voluntary movements are impeded, as well as the involuntary. Asphyxiating gases, and various other causes producing this state in a degree not immediately fatal, if continued in operation long enough to deprive the distended vessels of their tonic contraction, produce congestion of the pulmonary plexus. When recovery from the state of asphyxia is effected, the heart regains its full powers, and by its reaction upon the congested vessels, the congestion is converted into inflammation.

The effect of the more ordinary causes of pneumonia is very similar to this of asphyxia; congestion is first produced, which is converted into inflammation. The continued exposure of the surface to cold, constricts the external vessels, and drives the blood upon the internal organs; if any previous weakness or disease exists in the lungs, such as a deposit of tubercular matter, this organ becomes the seat of the congestion so produced, which the reaction of the heart converts into inflammation.

It is seldom, however, that the pneumonia, arising from asphyxiating causes, presents the characters of acute inflammation. The blood may have become so far stagnated in some parts that reaction cannot be produced, and congestion passes immediately into gangrene. Gangrene is by no means an ordinary termination to inflammation of the lungs. It was the opinion of Laennec that when this organ presents the appearances both of inflammation and of gangrene, it is the latter state which precedes and causes the former. This is now considered to be only occasionally, and not invariably the case. But those instances in which gangrene

results from asphyxiating causes are just those in which this state is most likely to precede, and, by its irritating effects, to give rise to the inflammation in adjacent parts. Chomel has related cases in which gangrene of the lungs has resulted from exposure to asphyxiating gases, in which he supposes that the first or congestive stage of pneumonia has passed immediately into gangrene. It appears not improbable that such was the case in the present instance, for the symptoms were at no time those of *acute inflammation*, which is that form most likely to *terminate* in gangrene. Neither was there any attempt set up to circumscribe the disease; the walls of the cavity were themselves in a state of *sphacelus*, presenting no definite boundary. The loose tissue of the lungs is not favourable to such a limitation, and the low character of the vascular action was likewise opposed to the effusion of good lymph requisite to this process. The extremities of the vessels leading to the gangrenous part were, however, closed, as was ascertained by examination, and proved by the circumstance that no hæmorrhage took place. The softened, almost purulent state of the muscular walls of the chest at one point, posteriorly, seemed as though an effort were then making to form an opening externally, for the discharge of the pulmonary abscess.

Besides these changes in the lungs, there was a considerable amount of tubercular disease, both of old standing, and in the form of miliary granulations of a recent date. The tuberculous affection, however, was of a slow and chronic character, and such as might not have seriously interfered with health for many years, though it may have served to aggravate the more acute affection hitherto considered.

The physical examinations during life afforded no very satisfactory signs of the amount of disease which existed within. The dulness of stroke-sound on each side, combined with the increased vocal resonance, showed that there was some unnatural condensation of the pulmonary tissue in both lungs; the crepitation heard in the lower part of the right lung, showed that, here at least, this state was connected with an inflammatory action, and the foetid odour and other characters of the sputa showed that this coexisted with gan-

grene of some portion. But no signs were obtained conclusive as to the existence of a larger cavity in the right lung. The nature of the circumstances, however, satisfactorily accounted for the absence of these signs. In an ordinary tubercular excavation, so long as it remains completely closed and unconnected with a bronchial tube, by which air may be admitted to the interior, no satisfactory physical signs of its formation are afforded; dulness of stroke-sound alone is produced, which may result from condensation alone. As some respiratory murmur was heard anteriorly, over the seat of the abscess, some portion of permeable lung must have intervened between this and the front walls of the chest; but the unusual tympanitic character of the stroke-sound observed in this situation, for some days before death, can only be accounted for on the supposition of some pneumothorax here, for the tissue of the lung did not present the appearances of emphysema.

The plan of treatment adopted in this case was locally antiphlogistic, combined with generally tonic and stimulant medicines, and regimen to support the strength, and enable the system, if possible, to throw off the putrid matter contained within the lung. But the symptoms were unfavourable from the beginning; and the extensive disease disclosed after death sufficiently accounts for the fatal result.

REMARKS ON INFLAMMATION.

To the Editor of the Medical Gazette.

SIR,

I HAVE abstained during the last two weeks from sending you any additional remarks upon the doctrines of inflammation as propounded in Dr. Copland's Dictionary of Practical Medicine, in order that he might have an opportunity of answering the arguments which I have advanced in refutation

of the main point of his position; but I have waited in vain. Engaged as Dr. Copland is in an extensive and laborious undertaking, as well as in practice, his time is of great importance, and it should not be heedlessly intruded upon. I am therefore willing to admit that he is not called upon to notice any trifling inaccuracy or inadvertence that may be discovered: but when an error is pointed out of so grave a nature as I conceive that to be which I have mentioned, I humbly submit that he is bound to notice it.

I shall now proceed to show how the error mentioned in my former letter has led to others. In paragraph 152, Dr. Copland says, "If the vascular system were *directly* under the dominion of the cerebro-spinal nervous system, all the functions of circulation, secretion, nutrition, &c., which are subjected to the organic nervous influence, would be liable to continual derangement, from the various impulses of the will and the passions." But does not every one know that these functions are constantly, and at all times, liable to be deranged by the passions? And if, moreover, Dr. C. had properly considered to what the operation of the will is limited, he would have perceived that all these functions may be dependent on the nervous system, without the will being able to interfere with them directly in any possible way. In these few words, therefore, we find both a statement implying a false assumption of facts, and a non sequitur. Dr. Copland also says in the same paragraph, "Excitement of the cerebro-spinal nerves has but little immediate influence upon the capillary circulation, excepting that of the countenance, as in the act of blushing; and then this is only temporary." It is indeed only temporary, but the tinge of colour may often, in any sensitive girl, be seen to spread from the face down the neck and bosom and along the arms even to the fingers' ends. It strikes me that if Dr. Copland could look at this question with unprejudiced eyes, he might see that all the phenomena connected with the visible and perceptible effects of mental emotions take place more readily in the young than in the old, because in them, the relative size of the brain, as compared with the body, is greater, and the whole secretory functions are carried on more rapidly than they are subsequently, when the full stature is completed. We cannot at all

understand why this relative difference should so constantly exist, if the cerebro-spinal nervous system has neither art nor part in the secretory function. The mental emotions, of which the effects are more immediately recognizable, are of two kinds, exciting and depressing; neither cause any new action, they either increase or diminish an action which is already established and going on, and is only interrupted or interfered with. The effect of these mental emotions which disturb the secretory function are the *evils* necessarily attendant on the arrangement of the nervous system, but when this subject is better understood it will be found that there is *much more* of good than of evil depending on the disposition of the brain and nerves, although according to the physiology of the present day the *latter only is apparent*.

Dr. Copland concludes the 152d paragraph with a statement which seems to me quite as much against fact as any of the others: he says, "In cases of severe injury to the spinal chord causing paraplegia, the lower extremities are not more liable to inflammation than in health." This I conceive to be against all experience; but, with the other erroneous statements which I have instanced, it springs directly from the original mistake of supposing inflammation to be caused by an exaltation of the nervous function: this opinion being first laid down as undeniable, every fact is forthwith forced into subservience to it.

Dr. Copland, at the end of his article on inflammation, refers to the works of Magendie, Syme, and a series of papers on inflammation, which I had the honour of contributing to the *GAZETTE* in the early part of 1835. But if Dr. Copland had carefully studied the facts referred to or contained in these writings, particularly the experiments of Mr. Syme, who shows that inflammation is constantly produced by the division of nerves, their functions being thus suspended or destroyed, it is scarcely possible to imagine that he could have fallen into the mistake of supposing the same state to be produced by an exaltation of their function. This is, indeed, so flat a contradiction, that it is not easy to understand how such a mistake can have arisen.

It would hardly be expected, after the mistakes I have instanced, that we should find Dr. Copland arrogating to

himself a peculiar power of discriminating nicely the value of different experiments, and of determining with superior sagacity the relative bearing of each. Yet so it is, as may be seen in paragraph 148, where, after enumerating first, second, and thirdly, of alleged oversights, he says, "But this is not all; the physiological or vital action of these agents has been neglected equally with the chemical action, and even with the changes they produce upon dead animal matter. These experiments abound, moreover, in other sources of fallacy, attributable to the means and aids used in ascertaining the effects, and to the subjects upon which they have been performed. Can it be believed, that all these circumstances, any one of which is sufficient to overturn the conclusions drawn from these experiments, have been neglected?" I do not like to lose this opportunity of recording my own testimony respecting the general accuracy and fidelity with which experimental facts are usually related and detailed. It does, indeed, too often happen that experiments instituted for a particular purpose do not warrant the inferences which have been drawn from them: for example, Vogel sees the red globules in the minute vessels crowd together, and adhere to their sides in the commencement of inflammation, whereas during the normal state they keep a central course and avoid the sides; and this phenomenon he supposes is produced by a change of attraction. In this instance there is no oversight, and the fact is accurately stated; but then the inference has nothing to do with it.

While, however, I thus endeavour to avoid being misled by false inferences, I should not think of withholding all praise and thanks from those to whose persevering industry we owe so much of both. Dr. Copland proceeds in the next paragraph (153) to illustrate what he calls the action of the vessels in inflammation, by referring to healthy phenomena; thus bringing together two states so utterly opposite that they cannot be compared; and so he goes on from one mistake to another, until all is inextricable confusion, in which I shall leave him for the present, remaining,

Your obedient servant,
J. W. EARLE.

Cheltenham, April 9, 1844.

TO THE
PHYSIOLOGY OF THE HUMAN
OVARY.

By CHARLES RITCHIE, M.D. Glasgow.

(For the Medical Gazette.)

[Continued from p. 8.]

PART II.

SECTION VII.—*Ovaries in individuals who had had children, but were afterwards menstruating.*

1. Mrs. W. aged 40 years: mother of six children, all of some age. Was menstruating six days before death. Inner surface of the uterus, as far down as its cervix, beautifully injected with thickly-set blood-vessels, arranged in circular arches, or rings, connected with each other in a kind of arborescent form, and covered by a thick layer of transparent mucus, interspersed with a few small clots of blood. Fallopian tubes empty, and small-looking, without either the usual mucus, or any blood. Vagina very red and vascular. Ovaries smaller than average. *Right*: No recent opening, but one lesion of surface, of about the size of a barley-corn, which opened into an oblong cyst, of size of a small pea, having in its centre a globular portion of colourless fibrin, and its walls of a rhubarb colour. *Left* ovary generally smooth, without any new opening on surface. One capillary-sized opening, of long standing, a small unruptured Graafian vesicle projecting, denuded of peritoneum in about two-thirds of its whole superficies, from surface of gland; also, another similar vesicle, over which a portion of the peritoneum was thinned, of size of a split pea, and two linear cicatrices, were what presented externally; and internally were no more than two small Graafian vesicles observable, and three cavities, with pulpy, somewhat yellowish walls, in which, although the blood was more or less absorbed, no corrugation of their coats had happened.

2. ———, about 40 years: one child early in life. Menstruating recently before death; her chemise still stained. Arteries of uterus injected with carmine in turpentine, and veins with indigo. No note of state of uterine cavity retained. Ovaries very deeply and extensively fissured. On

one a slit was observed in the peritoneal coat, nearly an eighth of an inch in length, permitting a hog's bristle to pass readily, by a minute circular opening, into a distended Graafian vesicle, which was found to be of an oval shape, and filled with a fresh florid coagulum of blood. The coats of this vesicle could not be separated. In the other ovary, there was a mamillated eminence, of the size of a small raisin, and of a dark colour, having a small linear division of the peritoneal coat, and a minute circular opening of the coats of the vesicle, which was found distended with a coagulum of an inky dark colour externally, but florid towards its centre. Coats of this vesicle were separated, although with difficulty, the inner being a mere pellicle, deeply dyed with the black matter of the coagulum, and the other also of very delicate structure, but much injected with vessels, some of which appeared to have been penetrated by the injection.

3. Mrs. —, seven children, youngest three years of age: menstruated four weeks before death. Several yellow bodies in various states; some of them exhibiting very distinctly an inner transparent pellicle, marbled with an inky pigment, penetrated by an opening from the surface, and collected into folds or plaits, running in a serrated manner into corresponding recesses in a more external coat, which was opaque, of a yellow colour, and five or six lines thicker than the inner. In another of these, apparently of longer standing, the outer coat separated easily from the stroma, and its cavity was contracted as if from corrugation.

4. Mrs. —, aged 46 years, mother of six children, the youngest four years of age: menstruated three weeks before death.

One ovary presented four considerable cicatrices, which appeared as if they had occurred in speedy succession; the older ones without vessels, the peritoneal coat being simply dyed black, while that which seemed the most recent was still surrounded by congested red vessels. This scar was about one-fourth of an inch in length, and about a line in breadth, and had behind it an elliptical cyst filled with intensely black blood. The walls of this cyst were somewhat thicker than thick post paper, of a light yellow or

ochre colour, beautifully convoluted on its external aspect, and having vascular striae dipping into its periphery from the substance of the ovary, while its inner edge presented also a serrated appearance, as if from minute and delicate duplications of the internal surface on itself. Corresponding to the other scars were two cysts, exactly similar to that described, except that the central clot had been reduced to a black line between the yellow convolutions; and in the third was a clot without any yellow envelope.

Other ovary had two scars with dark stains, the largest corresponding with a cyst of the size of a pea, the walls of which consisted of a yellow fatty matter deposited between two delicate membranes, the outer and densest presenting an exquisitely perfect brain-like aspect, and the inner, which was very delicate, being deeply stained with black blood. On removing this blood away from the inner surface, the latter exhibited something of the aspect of an unhealthy and slightly elevated ulcer, an appearance which was produced from the elevation of the internal pellicle by what looked like a soft, dirty-white, pasty matter, but which, on dividing the pellicle by slight scratches of the lancet, was found to be a layer of whitish-yellow granular matter, lying on the inner aspect of the external membrane. A black longitudinal line corresponded, internally, with the situation of the external cicatrix.

5. Mrs. M., aged 41, mother of seven children, youngest six years of age: menses present fourteen days before death. Arteries of uterus and ovaries injected with red size. Inner surface of uterus deeply painted with minute vessels, into which the injection had run; and at one point these were seen to shoot out at right angles from the uterine surface, like villi. The ovaries were occupied by several cerebriform cysts, two of which still communicated externally by foramina; and in one of these the yellow matter was intersected by numerous striae of a red colour, which were persistent on pressure, as if injected vessels.

6. Mrs. M., aged 35, mother of six children, youngest four years of age: menstruated a few days before death. Arteries injected with red wax. Uterine cavity, especially at cornua, of a deep dark colour, from the presence

of a lining of vascular jelly. Interior of ovaries, into which the wax injection did not penetrate, occupied by numerous "white bodies," of small size, some of which still contained vestiges of blood, while, externally, they looked like mere points of adipose matter; and, corresponding to a large and recent opening in the peritoneal surface of one of the ovaries, was a cyst of the size of a large boiled garden pea, full of dark blood, but having some of its fibrin completely deprived of colouring matter. This cyst, which was of the ordinary light fawn colour, and serrated or fringed appearance of the cephaloid bodies, was divisible into two coats, the inner surface of the exterior having the granular-coloured substance deposited on it in minute points or granules, which, when viewed in a bright light, resembled shining cellular or adipose tissue.

7. Mrs. C., aged 35 years, mother of three children, youngest three years of age: menses present a week before death. No opening on surface of ovaries, and no recent scar. Interior of one occupied by greatly enlarged and very vascular distended Graafian vesicles. Only two white bodies in glands.

8. Mrs. S., aged 35 years, mother of two children. Ovaries large. One marked with various smooth old cicatrices covering corpora cephaloidea and corpora lutea of various sizes, from that of a hemp-seed to that of a pin-head, and with one ecchymosed or vascular spot, corresponding to a distended Graafian vesicle which had reached the surface.

The other ovary exhibited six or seven more recent scars, one of which was very vascular, and still patent, and led into a cyst of the bulk of a garden pea, filled with a florid coagulum: its walls of the thickness of sheep-skin, of a bright yellow colour, beautifully convoluted, and having a strong resemblance, when viewed from within, to highly congested brain. On rubbing the interior of the cyst, even with the edge of a lancet, no lesion, cognizable with a magnifier, was produced, although it was not found possible to demonstrate an inner membrane. Externally, the cyst was easily dissected from the ovary, and displayed a thin but very vascular membrane, which, on boiling, could be separated from a more external investment.

9. — — —, aged 39 years. Four children, eighteen, sixteen, twelve, and six years of age. Menses present two weeks before death. Both tubes connected with ovaries by old adhesions, and one impervious, and its extremity enlarged into a sac of the size of a plum.

One ovary perforated by a hole leading into a cyst of size of a hazel-nut, its inner surface of a deep black colour, and containing a solid clot, externally of a coal black, and internally of a rose colour. In the same ovary were—1st, a discharged follicle of size of a horse-bean, without any coagulum, but having its inner membrane dyed black, and its outer yellow and beginning to contract; 2d, another in which this contraction was farther advanced, the inner membrane black, and the outer becoming white, cartilaginous-looking, and corrugated; 3d, three other similar bodies of smaller size from increasing contraction, yellowish externally, black internally, and coats of some thickness, and puckered up into wrinkles.

The second ovary also contained two large membranous cysts, in one of which was a black solid coagulum, and scattered throughout the gland were four small, empty, corrugated, corpora albida, yellowish white externally, black internally, with considerable thickness and elasticity of their coats.

10. — — —, aged 40. Five children, youngest five years of age.

One ovary marked by two elevated dark coloured vesicles of size each of a pea, filled with black coagula, but without any discernible external opening. The walls were of brain-looking matter, but neither an inner nor an outer membrane could be demonstrated, except in one.

Other ovary contained one white body, small, and distinctly hollow, but very attenuated in its coats.

11. Mrs. M—, aged 35. Three children, youngest five years of age. Menses present two weeks before death. No opening into either ovary, but in one, subjacent to an old cicatrix, was a cyst, in which was a partly melanotic, partly white and fibrinous clot, of about the size of a raisin, the cyst being capable of holding one a good deal larger. The inner surface of this cyst was not corrugated, but lined with a smooth, tenacious membrane, of about the thickness of writing paper; in some

places dyed of a reddish yellow, and in others of a jet black. External to this was another envelope of a red tissue, but much less tenacious than the former, and beyond this was a third distinct covering of similar structure.

In the *other ovary* there were two yellow convoluted bodies, and two large cysts containing black blood, one of which, as large as a common nut, had its coagulum nearly absorbed; but its dark dyed inner surface smooth, without any diminution of size, corresponding to lessened bulk of coagulum. Walls divisible, as was supposed, into two thin membranes, the inner appearing like a cobweb when viewed by transmitted light, and not distinguishable from other when examined otherwise.

12. Widow B—, aged 38 years. Four children, youngest two years of age. Menses regular.

One ovary contained four white bodies and a cyst, the inner surface of which was covered by an ash-coloured pigment, which could easily be scraped off, leaving inner surface of vesicle, which was vascular, clean, without any distinguishable breach of its substance, unless it was, that at one or two points it was, as seen by the magnifier, elevated into very minute fungiform projections.

The *other ovary* was gathered at one part into a mamillated tumor, having the peritoneum much injected with minute florid vessels, under which an enlarged Graafian vesicle was found, and the gland was occupied also by four white bodies and one bright yellow cyst, on rubbing the inner surface of which, a semifluid pasty substance, giving colour to the cyst, could be detached, exposing the inner highly vascular surface of the cyst, stained in several places with the yellow matter, but covered over with numerous minute, slightly raised, and florid granulations, or projecting blood-vessels.

SECTION VIII.—*Ovaries in women who had had children, and in whom menstruation, re-established, had been arrested by disease.*

1. Mrs. B—, aged 30 years. One child. Death from phthisis.

Surface of ovaries occupied by transparent miliary-sized vesicles, some of

which were protruded from the peritoneal coat to nearly their whole extent. Interior of each ovary contained several white bodies, and one of them a vesicle filled with a melanotic coagulum, which although, judging from the minute size of the cicatrix of what had been its external opening, of considerable standing, had undergone little absorption.

2. Mrs. M—, aged 43. Had one child, and several abortions. Delicate health and amenorrhœa for two years. Both ovaries of good size, with several faint scars, interspersed with small vascular elevations of the peritoneal surface. Internal structure a vascular pulp, oozing out fluid from numerous capillary sized points, and sprinkled with vesicles, visible only with a magnifier, and having extremely delicate coats. No white, yellow, or other body visible.

3. ———, said to be aged 50 years, but asserting that she had menstruated four months before death, which arose from dropsy.

One ovary had traces of several old scars, and various spots of a scarlet and one of a purple colour, on its surface, the latter corresponding internally with a vesicle filled with fluid blood: ovary contained several well-marked hollow white bodies, and some very small-sized yellow ones, but no unbroken vesicle was observable by naked eye.

Other ovary had some similar scars and purple spots on surface, and internally several corpora lutea, or vesicles with thin coats dyed yellow, and their inner surface still smeared with blood. No unbroken vesicles.

4. — Hill, aged 25. A prostitute, who was said to have had several abortions. Uterus small and thin, its cavity obliterated, except at one cornu. Orifice large and patent. Ovaries enveloped in broad ligaments and adventitious membrane, on the surface of which were various cysts, having a resemblance to extruded Graafian vesicles. Interior of glands contained no yellow or cephaloid, but a number of white bodies, some unbroken vesicles, and a few bloody cysts, in one of which the coagulum was as large as a pea, very soft, of a snuff brown colour; and the coats of the vesicle were deeply stained, but without any thickening or deposit.

SECTION IX.—Ovaries in individuals who had had children, and had ceased to menstruate from age.

1. ———, aged 50 years. Mother of four children. Uterus healthy.

One ovary size of a dried horse-bean, much corrugated, with inner structure solid, dry, and containing two cream-white bodies, but no vesicles.

Other ovary as large as a kidney bean, and containing an inky-coloured empty vesicle (corpus nigrum). One white body, but no unbroken vesicles.

2. Widow C——, aged about 54. Mother of a large family.

Left ovary indented with numerous fissures, and one unbroken Graafian vesicle, with vascular coats. Internally there was a cyst of size of a dried pea, of a very deep yellow colour, and having a dark-coloured pellicular lining, as if of inner membrane slightly dyed black; also two very distinct hollow and very white bodies.

Right ovary similarly indented with the left, and at one point particularly, where the peritoneal coat was still of a black colour, the depression was found to cover a cerebriform cyst of a linear shape, traversed by a melanotic line, and coated with an inner membrane. Ovary also contained four white bodies, but no unchanged vesicles.

3. Mrs. S——, aged 58. One child, about twenty years of age. Ovaries much denticulated by fissures, and on surface of right ovary was a vesicle of size of a pea, filled with a transparent yellow fluid. Internally were two corpora nigra, and some white, but no cephaloid, or yellow bodies, or vesicles.

3a. ———, a woman, upwards of sixty years of age, who had had a numerous family. Vagina large and smooth. Os uteri wide, more than an inch in length, its edges hard and denticulated, but without ulceration. A small flattened polypus hung from the situation of the Nabothian follicles. Tubes impervious at uterine extremities. Ovaries strongly fissured, and of the shape and nearly the size seen in children, and having a delicate vesicle, of the bulk of a pin-head, extruded from the surface of the one, and a minute copper-coloured punctum in the other. Interior of each consisted of a succulent pulp, which communicated to the finger the impression of being formed of numerous very minute grains, and, when examined with a

magnifier, some of these were ascertained to be vesicular, although of the most fragile structure, and to be the source, along, as was supposed, with a multitude which could not be so demonstrated, of a copious oozing of fluid which issued from the cut surfaces of the glands. There were also two well-formed and vascular, but delicate, Graafian vesicles, of the size each of a millet-seed, observed in the sessile edge of one of the ovaries.

4. Mrs. S——, aged 64. Mother of four children, youngest twenty-four years of age. A very healthy woman, who died of fever. Ovaries much atrophied, and consisting almost wholly of peritoneum, imbedded in which were four hollow white bodies, one as large as a pea. On the surface of the ovaries, and in the broad ligaments adjacent, were numerous vesicles of different sizes; those nearest ovaries arranged in clusters; some of the size of millet seeds, and transparent; others larger and opaque; and some of those which were furthest removed from the ovaries, were solid, and consisted of a stony matter, which, on cutting the membranous capsular investment, was easily enucleated.

5. ———, aged 75. Os uteri enlarged and fissured, as if it had been once gravid. Ovaries attenuated, but contained, the one six or eight, and the other nine, small-sized corpora albida, and a very succulent and vascular pulp, oozing out fluid profusely, and having an indistinct appearance with a common magnifier of containing numerous small sized and very fragile vesicles. Fallopian tubes were impervious near to the uterus. The surface of one ovary was studded with numerous eyes, or very minute but distinct vesicles, like ovisacs, some of which had given way, and left patent pores, precisely as in the other non-menstruating periods of life. There were two or three large vesicles in the broad ligament, from which slender pedicles could be traced connecting them with the ovary.

6. Preparation of Dr. Paterson's, Anderson's Institution. Uterus and appendages of a woman aged 103 years, and the mother of several children.

One ovary reduced to size of a boiled garden pea, and the other smaller; one of them having one or two triangular, and the other several very distinct punctuated cicatrices on surface. Inter-

nal structure of glands a homogeneous pulp, but gathered into a solid tissue at apices, and with some indistinct indication of a vesicle.

Air was made to pass with difficulty along one tube from the uterus to the pavillon; but on some subsequent attempts this could not be repeated, and in the other tube failed altogether, the obstruction in both being at the uterine extremity of the tube, near to its termination.

[To be continued.]

DR. RAMSBOTHAM'S REPORT ON THE ROYAL MATERNITY CHARITY.

To the Editor of the Medical Gazette.

SIR,

You did me the honour to publish, for four successive years, a statistical summary of the obstetric cases which occurred in the Eastern district of the Royal Maternity Charity, under my superintendence. Engagements, which pressed heavily on me, have prevented my forwarding these accounts to you since the year 1831; but, as I consider such documents valuable additions to our medical information, I will, with your leave, resume them now, and supply the particulars from time to time, down to the present date. I should mention that there are two other districts in this charity, a western, and a central one, each under the care of a separate physician; the statistics of which are not included in the subsequent reports.

I am, sir,

Your obedient servant,

FRANCIS H. RAMSBOTHAM, M.D.

14, New Broad Street,
April 17th, 1844.

During the year 1832, there were delivered in the Eastern District of the Royal Maternity Charity, under the superintendence of Dr. F. H. Ramsbotham—

2344 women,—Of which cases

33 were twins—one in about every 71 cases: of these in 18 cases both heads presented; in 10 the presentations were head and breech, or inferior extremities; in 3 both were breech, or inferior extremities; and in 2 one presented with the head, and the other

transversely. In 11 of these cases the children were both boys; in 11 both girls; and in 11 one girl and one boy.

1197 children were males.

1180 children were females.

2320 were presentations of some part of the head; of which 8 were face presentations—one in about every 297 births; and one was an ear presentation.

51 were presentations of the breech, or some part of the lower extremities—about one in every 46½ births; of these 16 were twins.

6 were transverse presentations—about one in every 396 children: of these, two were each a twin; one at 7 months was expelled doubled, or by what is called the "spontaneous evolution," while I was present; another at 7 months, *turned*; the other four were at full time; and in all the operation of version was performed.

In 2 the placenta was entirely, and in 1 partially, implanted over the os uteri—one in every 781½ cases. In the instances where the os uteri was completely closed by the placenta the children were *turned*; both women had lost a large quantity of blood before the operation was performed, and one died in three days from the effects of the hæmorrhage. Where the placenta was partially over the mouth the membranes were ruptured, the flooding ceased immediately, and the fœtus was expelled in five hours. In all these cases the children were born dead.

11 were complicated with dangerous hæmorrhage before delivery, *not* the result of placental presentation—about one in every 213 cases. All these children were born naturally, some time after the membranes were artificially broken—6 living, 5 dead; of these latter 5, three were premature; and one of them was a footling presentation.

In twenty-five cases the placenta was retained within the uterus, either by atony or irregular contraction of the uterine fibres, or by morbid adhesion between the placental and the uterine surfaces; so as to require the introduction of the hand for the purpose of removal—one in about every 94 cases. With all these there was more or less hæmorrhage: one of them was a twin case; the woman died on the fifth day after delivery from the effects of the loss of blood: another was after craniotomy had been per-

formed; the woman died in a week from hysteresis. One woman was in the last stage of Asiatic cholera when she was taken in labour; the child was expelled dead; the placenta was retained by inertia, and the woman died soon after its extraction. Two were premature deliveries; in one of them labour had been artificially induced, and the child was dead. One patient had a slight attack of phlegmasia dolens after delivery.

5 were complicated with alarming hæmorrhage after the natural expulsion of the placenta—about one in every 469 deliveries; two of these women died—one within an hour, the other three or four hours after. The latter case was a breech presentation.

2 women were delivered by craniotomy—one in every 1172 cases. In both these instances the pelvis was considerably narrowed in the conjugate diameter at the brim; one was a first labour. I have induced labour prematurely for this woman five or six times since. The other was a fifth child: I delivered her of her first by craniotomy in November 1825. Since then she had had one living, and two dead children, born naturally, after many hours of severe labour. When I saw her the funis was prolapsed, and the arteries had ceased to pulsate. I had great difficulty in extracting. The placenta was firmly adherent to the uterus, and required much effort to separate it; there was also considerable hæmorrhage. On the third day she was attacked with hysteresis, and died in a week from the date of delivery.

2 were delivered by the long forceps—one in every 1172 cases; they were both first labours: the pelvis in both cases was slightly distorted at the brim, with the principal part of the head above it. In one case the left ear could just be touched behind, or rather above, the pubes; in the other, neither ear could be felt. Both women did well; both children were born living; but one survived its birth only a short time. In one case I was obliged to remove the placenta from the uterus by the introduction of the hand, in consequence of irregular contraction around the mass.

One was complicated with true puerperal convulsions, which came on ten days after delivery. The woman suffered five or six fits within three hours,

and was comatose: she was bled and purged freely, and the next day was quite well. It is very unusual for convulsions to occur so long after delivery; and I suspect this woman had been drinking.

In 4, premature labour was induced—one in every 586 cases; in three, by the use of ergot, without any other means having been had recourse to: in each of these cases the pelvis was contracted in its dimensions. The time chosen was between the seventh and eighth month of pregnancy; two of the children were born dead—the other alive; but ten hours after its birth it was seized with convulsions, of which it died. In the other case the patient was suffering under a malignant and fungoid tumor, situated on the right buttock, considerably larger than an orange, and increasing rapidly in size. It was her seventh pregnancy. Upon consultation held, it was agreed that the tumor must be removed; that to do so during pregnancy would be more than usually hazardous; and that if she were allowed to go to her full time, the probability was that the tumor would by that time have acquired such a magnitude as to render the operation very formidable. I therefore punctured the membranes when she was seven months advanced, and the child was born living. In twenty-four days she was received into the London Hospital, and the next day the tumor was removed; it was attached to the fascia of the glutæus. In eleven weeks she was dismissed well.

13 women died within the puerperal month, or from puerperal causes—being about one in every 180½ cases; 10, however, only as a consequence of labour, or one in about every 234½ cases; for two died of cholera, at that time raging, and one of chronic pulmonary disease.

2287 children were born living.

89 were still-born—being about one in every 25 births.

Of the Deaths,

I was on the third day after delivery, with violent vomiting and purging; the patient having, on the previous days, taken meat, porter, and brandy and water.

3 from peritonitis; one on the fifth day after delivery of twins; one on the ninth; and one on the fourteenth day.

4 from the effects of hæmorrhage: one three hours after delivery under a placental presentation; one a few hours after the natural expulsion of the placenta; one in an hour after delivery of twins—the labour had been lingering; and one on the fifth day, there having been an adherent placenta. This was also a twin case.

1 of hysteritis a week after delivery by craniotomy; this case was also complicated by an adherent placenta.

1 suddenly, on the eighth day after delivery: a very careful examination threw no light on the cause of death.

2 from cholera; one immediately, and the other two hours after delivery.

1 from chronic pulmonary disease.

Of the still-born children,

28 were premature.

13 were putrid, at full time, or nearly so.

6 were breech presentations, at full time, or nearly so.

1 was a transverse presentation.

2 were delivered by craniotomy.

2 were under an entire placental presentation.

1 was under a partial placental presentation.

5 were after dangerous accidental hæmorrhage.

5 were under lingering labour.

1 was monstrous.

With 2, premature labour was induced.

With 4, the funis prolapsed by the side of the head.

With 4, the funis prolapsed by the side of the breech.

With 2, the mothers were dying of cholera.

13 were at full time, or nearly so; head presenting, not putrid, nor delivered by art.

STATISTICS OF MIDWIFERY.

CASES IN PRIVATE PRACTICE.

To the Editor of the Medical Gazette.

SIR,

THE late Dr. David D. Davis, in his "Elements of Operative Midwifery," says: "Of all the questions that may occur during a deliberate consideration of this subject, none can exceed in importance that of the average frequency with which we should appeal to the

instrumental resources of our art. I am sorry to say, that we are not in possession of sufficient documentary evidence to enable us to decide this point; whilst the evidence we have is of so unsatisfactory and conflicting a nature as to afford us but very slender materials for useful practical induction."

Dr. Davis concludes his references and his reasonings on this grave question with the following passage:—

"Upon the whole, therefore, I am much inclined to the opinion, that it cannot be absolutely necessary to have recourse to the use of the forceps or the lever more frequently than once in three hundred, or at most in two hundred and fifty cases, in order to insure for puerperal women the greatest possible advantages attainable from the employment of these obstetric powers."

In furtherance of the important object which Dr. Davis had in view, I cannot resist the temptation, through the medium of your valuable journal, of calling the attention of the profession at large, more particularly of accoucheurs, to the following statement of facts:—

My uncle and partner, the late Dr. Jarvis, was a great enemy to instrumental aid in midwifery cases, averring "that *nine times out of ten* the necessity might be avoided by prudence and by patience."

Dr. Jarvis commenced his medical career in Margate, as a general practitioner, on the 1st of January, 1788, from which time, to the 1st of January, 1816 (twenty-eight years), he attended eight hundred and ten labours, of which *one* (the seventh) was a triplet case, and *seven* were twin cases—one in one hundred and fifteen. I have no record of the small number of times Dr. Jarvis used the forceps, or the vectis, or had recourse to turning; but it is certain that he never lost but one midwifery case—a Mrs. C., from hæmorrhage, on the 12th of June, 1815, the day after her delivery.

From the 1st of January, 1816, to the 1st of January, 1844 (another twenty-eight years), in conjunction with Dr. Jarvis to the 1st of January, 1827, and with the aid of a visiting assistant from that day, 1349 labours were attended in my own practice, of which *twelve* were twin cases (one in one hundred and twelve), *three* were forceps cases, *two* were

vectis cases, and nine were "turning" cases, one of which, a Mrs. B., died from hæmorrhage, on the 21st of July, 1819, two hours after her delivery. This is the only midwifery case I have ever lost.

Thus, from the 1st of January, 1788, to the 1st of January, 1844 (fifty-six years), two thousand one hundred and fifty-nine women have been delivered, (with only two deaths) of two thousand, one hundred and eighty children (males, 1136—females, 1044); and thus, of the last thirteen hundred and forty-nine labours, three, and *three only*, required the use of the forceps, being rather less than *one in four hundred and forty-nine*.

I am, sir,

Your obedient servant,

JOSHUA WADDINGTON, M.R.C.S.

Consult. Surgeon to Royal Sea-Bathing Infirmary.

Marine Terrace, Margate,
April 17, 1844.

RECORD OF CASES.

By THOMAS MAYO, M.D. F.R.S.

Physician to the Infirmary of St. Marylebone.

(For the Medical Gazette.)

[Continued from p. 73.]

Ileus.

CASES of ileus attended by stercoraceous vomiting, yet terminating favourably, are uncommon. On this account, as well as for its other merits, the paper by Sir George Lefevre, read at the Med. Chirur. Society, on the 26th of March, was valuable. Regarding the case there portrayed, therapeutically, we may observe, that leeches, the internal use of hydrocyanic acid, and doses of croton oil, were efficacious in it; that opiates were administered without benefit.

The following unsuccessful case of similar obstruction, which occurred at the Marylebone Infirmary in 1841, may in some points of treatment be contrasted with this: at any rate the juxtaposition of unusual cases is advantageous. Besides, the case, which I shall now record, if it cannot suggest effective treatment during its course, is instructive in its autopsy.

H. Dunn, æt. 29, of a thin muscular frame, reported of intemperate habits, was admitted May 10th, 1841, as labouring under obstinate constipation and pain of the abdomen. He stated that on three former occasions he has

857.—XXXIV.

suffered similarly. He was seen by me at 8 P.M., described as having had no motion for four previous days, but as having passed a little fecal matter that morning with an Enema Terebinthinæ. He had severe griping pains, but the abdomen was not tender; his pulse was quick, sharp, and rather hard; his breathing excited in the lower lobe of the left lung anteriorly, where he complained of pain from deep inspiration. Hydrarg. Chlorid. gr. iij. had been given him, and Misturæ Magnesicæ c. Magnesicæ Sulphat. ziss. sextis, had been directed. I ordered that he should be cupped ad 3xij. at the painful point of the thorax.

11th, 2 P.M.—Small watery evacuation. Breathing completely relieved; pulse softened. Tongue dry, brown, coated.

Ol. Croton. ℥j.; Ext. Colocynth. Co. gr. x. in pil. divis statim. Enema Terebinthinæ vespere.

12th, 1 P.M.—Severe griping pain had ensued last night on the above medicines, which was appeased by a grain of opium, and then Ext. Colocynth. Co. gr. x. had been repeated with Olei Crotonis, ℥ij. Some sleep had been obtained in the course of the night, and the griping is now less severe; but no evacuation had been obtained. The urine, however, was plentiful; the tongue less dry, though not less coated and brown; the pulse soft. Nausea was now first complained of. The abdomen was swelled and flatulent, but with little tenderness. He lies on his back with his knees raised. I directed Elaterii, gr. iij. as a suppository, to be followed by a warm bath, and at 5 P.M. I found that one small hard motion had resulted. I then directed Hydrarg. Chlorid. gr. x. tertiâ quâque horâ ad 4tam vicem; of which, it may be observed, three doses were taken; good beef-tea, and brandy and water, were allowed.

13th, 8 A.M.—During the night I found stercoraceous vomiting had occurred, to the extent of three potfuls! of loose, lumpy, dark fecal matter, of an olive colour, with great relief of pain and tympanitic distension, but extreme prostration of strength. Pulse very feeble; skin cold and clammy; no nausea at present; extreme restlessness; he had passed a sleepless night.

Sumat. Hydrarg. Chlorid. gr. iv.; Opii, gr. ij. 4tis ad 3tam vicem, si opus sit;

L

the object being to obtain rest without increase of constipation. Strong beef tea, in enema or by the mouth, was ordered.

1 P.M.—He was less restless; no farther vomiting; his pulse, after the first dose of calomel and opium, had become stronger and more distinct—84 beats in the minute; he had turned on his side; and hiccup, which existed in the morning, had ceased. He takes brandy and water. Occasional griping; generally little suffering; tongue moist; abdomen less tumid; urine plentiful; mind collected.

7 P.M.—He has taken three doses of the pills, and his bowels have acted loosely with a broth enema; no sickness. He is anxious to obtain sleep.

Sumat. h. s. Hydrarg. Chlorid. gr. iij.;
Mist. Camphoræ, ʒj.; Tinctura Opii,
ʒxl.

He slept well through the night, and died suddenly at 7 o'clock the next morning, choked apparently by excessive fecal vomiting, which occurred suddenly during his sleep.

With great difficulty we obtained leave to make a hasty examination of the abdomen, but neither of the thorax nor the brain. The rugæ of the stomach and duodenum were very large, and highly injected with blood, as also, in a lesser degree, were the intestines generally. The cæcum very large, containing some fecal matter similar to that rejected by vomiting, of which there was a large quantity also in the colon; this intestine was large. The ileo-colic valve healthy; no ulceration and no stricture until we arrived at the rectum, of which about ten inches were so constricted as scarcely to admit a quill; its coats otherwise normal, and of a very white colour. The above were the only morbid appearances of the viscera of the abdomen.

Now, in reviewing the treatment of this case, I may observe—1st, That the quantity of blood obtained from cupping on the thorax would have been more probably beneficial if taken by leeches spread over the abdomen, as in Sir George Lefevre's case. For the mucous membrane of the intestines was highly injected with blood; and our exploration of the thorax gave us no reason to presume inflammation in that quarter. It is likely that the patient's pain in respiration was connected with the

descent of the diaphragm, and action of abdominal muscles on an inflamed intestinal canal. Large depletion would have been ill borne, as there was much depression of power; indeed, the constipation itself had no doubt lasted much longer than the time mentioned by the patient.

2dly, We may observe that the introduction of bougies into the rectum is indicated, in this case, by the seat of the stricture, and might have relieved it; a tendency to downward evacuation having been, indeed, established by the other means employed, before the accidental termination of the case.

In the following case, of which I have but slight memoranda, a more successful termination was obtained, also by a very accidental circumstance apparently removing that obstruction on which stercoraceous vomiting had depended.

I saw a lady, in the autumn of 1842, in consultation with Dr. Watson, Dr. Ashburner, and Mr. Arnott, who had laboured under acute symptoms of ileus, including fecal vomiting, for several days. She was justly considered by those gentlemen in great danger. She was aged; her visage was contracted and sunken; her tongue brown and dry; pulse feeble; her general appearance indicated restlessness and distress; and the curative means employed—calomel, and active aperients—had been ineffectual, though applied earnestly and skillfully. A complete examination was now again made of the abdomen, *with much pressure of it in various parts*, and a plan for the prosecution of the case laid down. In the afternoon of the same day, Dr. Ashburner called on me, and informed me that after our leaving her the patient had said that the pressure made had moved something, which had, as it were, descended through the bowels; in fact, she had, in the course of a short time, expelled an oval calculous concretion, about two inches long, with entire, and, as it proved, permanent relief of all her symptoms.

In a fatal case of ileus, which occurred to Dr. Abercromby, he gives the following post-mortem phenomena:—"The upper half of the small intestine was distended and inflamed, with considerable exudation. The lower half was collapsed, empty, and of a healthy appearance. At the place

where the distension ceased, there was found a large biliary calculus, four inches in its larger circumference, and three and a half in its smaller. The common duct was enlarged, so as easily to admit a finger.*

[To be continued.]

CASES OF DIABETES MELLITUS :

WITH PRECISE OBSERVATIONS CONCERNING
THE INFLUENCE OF ANIMAL DIET UPON
THE URINE.

By JOHN PERCY, M.D. Edin.

Physician to Queen's Hospital, and Professor of
Organic Chemistry, Queen's College,
Birmingham.

(For the London Medical Gazette.)

CASE I.—Admitted in-patient of the Queen's Hospital, September 15, 1843, Edward R—s, æt. 37. Dark hair and eyes. Short stature. Married twelve years, and has one child eight years old; his wife has not since been pregnant. By trade a bridle-cutter. He has been accustomed to work in a top story, which, during the summer, was exceedingly hot, and during the evenings of winter was rendered hot and oppressive by gas-lights. Of general good health. Never remembers having been confined to-bed by any illness. Habits temperate, though occasionally he has been guilty of slight excesses. Had syphilis eighteen years ago. A year ago an eruption of minute millet-like spots, not attended by itching, appeared on the fore-arms; previously, had never any cutaneous affection. Has never spat blood.

About seven months ago, he began to suffer from thirst, and to pass urine more frequently than natural, especially during the night. Afterwards, his attention was directed to white spots on his breeches, occasioned by the evaporation of urine. He has lost flesh: last Christmas (1842) he weighed 143 lbs., and three months ago his weight was reduced to 126 lbs. Perspires but little. Mouth dry and parched. Taste of a "sourish nature." No particular increase of appetite. In a morning has an uneasy sensation referred to epigastrium, relieved by taking food. He is ill-tempered and peevish, without any assignable cause. No headache. Has

lost strength and desire for exertion. Lower extremities soon become cold. Food does not lie heavy at the stomach; occasionally much flatus, which escapes both by the mouth and anus; bowels generally confined. Tongue rough, white, coated, moist. His desire for sexual intercourse is diminished, though he still retains the power. No irritation of the extremity of the penis. No hereditary predisposition; nor is he aware that any of his relatives have ever been affected in a similar manner to himself.

Accurate observations respecting the diet and urine are appended in tables.

September 15th. — Had a vapour-bath, and perspired freely afterwards. Dryness of mouth relieved. Ordered—

Pil. Sap. c. Opio, gr. v. bis die; Ol. Ricin. p. r. n.

23d.—Capiat Creasot. gtt. j. ter die.

27th.—Dryness of mouth considerably relieved. During the last two or three days has had occasional abdominal pain, without purging. Feels pretty well. Appetite increased. On the 25th had a biscuit.

Rep. Pil. Sap. c. Opio, ter die; Intermitt. Creasotam.

October 4th.—Pain in the bowels, with slight purging. No dryness of the mouth. Does not relish his food. Pulse languid. Skin moist. Has perspired freely.

7th.—Complains of more thirst this morning than he has since the first week of his admission. Tongue white and coated. Passed urine twice in the night. Could take more meat.

11th.—Less dryness of the mouth. Tongue moist and slightly coated. Skin moist. Feels "better in himself."

To take occasional lime-water flavoured by sassafras chips. Omit. medicamenta.

21st.—Two days ago he began to take cod-liver oil (the white variety obtained from Mr. Morson, London). Has taken half an ounce twice daily. Passed urine only once last night. Weight yesterday, 120 lbs.

24th.—Has been purged several times.

Capiat. Mist. Creta, c. Conf. Aromat. Intermitt. Ol. Jecoris Aselli.

27th.—Still slightly purged.

℞ Sulph. Ferri, gr. ij.; Opii, gr. iss. M. Ft. Pilula. capiat. j. ter die. Repet. Ol.

* Abercromby on Diseases of Abdominal Viscera, p. 125.

November 18th.—Feels very well. No dryness of mouth. Pulse improved in strength. Skin warm and moist.

25th.—As before. Tongue moist and slightly coated; it has all along maintained this character. Has not taken the oil for two days, in consequence of his stock having been exhausted. Can now take five or six table-spoonfuls without inconvenience, daily. Relishes his food. Passed urine three times last night.

December 2d.—Skin moist. No dryness of mouth. Tongue pale and moist.

16th.—Appetite not quite so good. In other respects as before. Weight 118 lbs.

Omitt. Oleum. Cont. alia.

January 6th.—Is becoming weary of a pure meat diet; does not relish his breakfast. No complaint of thirst or dryness of mouth. Tongue thickly coated posteriorly. Complains of soreness of throat. Slight specks of ulceration on the tonsils. Has perspired freely of late. Skin moist. Pulse 82 (standing), moderately compressible. Feels no depression to-day. Of late has risen once every night to pass urine. Since the 23d of December has been taking a drop of creasote in mixture three times daily.

℞ Argenti Nitratis, gr. ij.; Mice Panis, q. s. M. Ft. massa, et div. in pil. xij.; Capiat j. ter die.; Pil. Sap. c. Opio, gr. v. bis quotidie; Cont. oleum. Om. alia medic.

17th.—Diarrhœa last evening.

Cap. Pulv. Ipecac. co. gr. x. ter die.

He had occasionally suffered from diarrhœa, which I was inclined to attribute to the cod liver oil; I accordingly desired him to intermit it, but the diarrhœa occurred during the periods of intermission.

20th.—No complaint of thirst or dryness of the mouth; he feels comfortable, and desires to resume his work. He left the hospital on the 25th, still continuing under my care as an out-patient. I now determined to watch the effect of opium gradually increased, and I again prescribed—

Pil. Sap. c. Opio, gr. v. to be taken twice daily.

29th.—No thirst or dryness of mouth. Appetite good. Can take exercise without fatigue. Perspires on exertion. Complexion improved. Tongue natural.

Bowels regular. Passed water twice last night, and once the night before. Has not taken any vegetable food, except tea and coffee, without sugar. Fat bacon agrees well with him; no uneasy sensation at the stomach after taking fat. Not the smallest unpleasant effect from the opium pills.

February 7th.—As before.

Capiat. Pil. Sap. c. Opio. sex quotidie. (The number having been gradually increased).

March 2d.—Has been at work during the last fortnight. A few days ago, on returning from his work at night, he caught a severe cold, followed by shivering, colicky pain, and diarrhœa. I prescribed chalk mixture with aromatic confection, and Tinct. of Opium, and a powder composed of Pulv. Jacobi veri and Pulv. Ipecac. co. This morning there is an eruption about his mouth; diarrhœa; debility; tongue foul; has taken of late a biscuit daily, and this morning about four ounces of common bread.

Cap. Pulv. Ipecac. co. gr. x. ter die.

℞ Ammon. Carb. 3j.; Aquæ Anisi, ℥viij.; Solve. Cap. ℥j. ter die.

9th.—Having requested him particularly to examine his urine in respect to acidity instantly after evacuation, he reports that uniformly litmus paper was reddened by it. The examination was repeated several times, and uniformly with the same result. From my knowledge of the patient, I am satisfied that these results may be depended on. These observations were made to test the assertion of Dr. Alldridge, contained in a recent number of the Dublin Medical Journal, namely, that the urine of diabetes mellitus is always *neutral* to test paper, immediately after evacuation. Although I would not attempt to oppose the results of a single case to those of Dr. Alldridge, yet I may remark that I have always found the reaction of diabetic urine to be decidedly acid in every case which I have had an opportunity of examining.

I now append tables of the diet, and the quantity of urine passed daily. Any conclusions which may be drawn from these data I shall reserve for a future communication respecting the treatment of the disease in question.

Table of the Diet of Roberts, during his residence in the Hospital.

By gluten bread is meant, bread made with wheat flour, from which the greater part of the starch had been removed by washing. It was carefully prepared in the hospital. The liquid which he drank besides milk and beef-tea, was weak tea or coffee without sugar, and water flavoured with sassafras; the quantity may be found by subtracting the amount of beef-tea and milk in the following table from the quantity of liquid indicated in the tables marked A and B. Weights all avoirdupois.

The absolute amount of liquid drunk during the residence of the patient in the hospital, a period of 129 days, was 536½ lbs.; whilst the amount of urine voided during the same period was 612 lbs. 2½ ozs. The average specific gravity of the urine was 1036°. I can vouch for the accuracy of the foregoing tables, the observations on the urine having been made by an intelligent apothecary, Mr. C. Palmer, who was my laboratory assistant during six months.

Chemical observations respecting the urine.

I prefer giving these observations as they occur in my journal.

Sept. 15.—Urine passed to-day. Colour, pale straw. Clear, without sediment. Usual odour of diabetic urine. Acid, reddening litmus. Sp. gr. 1038°. I evaporated some of this urine to the consistence of syrup over the steam-bath, and added to the residuum twice its volume of nitric acid, of sp. gr. 1·2. On the following morning a beautiful crystalline mass of nitrate of urea was diffused through the liquid.

16th.—Urine rather deeper in colour. Odour urinous. The patient was, immediately on admission, restricted to an animal diet, but he had previously taken a considerable quantity of bread and other amylaceous matter.

18th.—Colour, pale brown, like that of ordinary urine. Smell, urinous. A considerable deposit of rhombic plates of uric acid. Sp. gr. 1039·7; temp. 71·5 F. I fermented 1000 grains of this urine with a minute quantity of yeast precisely in the manner described in a former communication to the GAZETTE.

23d.—Potass apparatus after fermentation . . . 626·87

18th.—Ditto ditto before fermentation . . . 603·50

Increase due to carbonic acid 23·37

This corresponds to 52·67 grains of grape-sugar (C₁₂ H₁₄ O₁₄).

Nov. 25th.—Urine passed to-day. Pale. Slightly turbid from flocculent matter; turbidity instantly removed by a minute quantity of nitric acid. No deposit of uric acid. Reaction very feebly acid.

Jan. 15th.—Acid. Slightly turbid from mucous flocculi. No deposit of uric acid. Sp. gr. 1042°; temp. 51° F.

Urine was passed from the morning of 14th to that of 15th. The whole quantity amounted to 4½ pints. Of a portion of this I made the following quantitative analysis:—

<i>Analysis of 1000 grains.</i>			
	Solid matter	105·50	
Water			894·50
Sugar			40·12
Urea			12·16
Uric acid			0·16
Indeterminate organic matter			44·58
Chlorinic, carbonic*, phosphoric, and sulphuric acids			6·78
Potass (copious) and soda			
Phosphoric acid			1·70
Lime and magnesia			
			1000·00

500 grains left by evaporation in vacuo over SO₃, 55·83 grains, which, by further evaporation in Berzelius' apparatus at 212°, were reduced to 52·75, at which amount I have estimated the solid matter in the foregoing analysis. The urea was separated in the usual manner, from the fermented urine by evaporation, treating with alcohol and nitric acid of 1·2. I made at the same time a comparative experiment concerning the extraction of the urea, by the same process, from the unfermented urine.

500 grs. of the fermented urine, furnished of nitrate of urea . . . 12·41

500 grs. of the unfermented ditto, ditto ditto . . . 6·76.

On the addition of NO₃ in the latter case, slight effervescence was occasioned.

We cannot but be struck with the large proportion of indeterminate organic matter indicated in the analysis. Thinking that possibly some defect might have existed in the determination of the sugar, I fermented between two and three pints of the same urine with yeast, keeping the mixture, during the whole process, in a warm place by the fire.

100 grains of this fermented urine, evaporated over the steam-bath, and dried during many consecutive hours at 212° F., furnished 6·65 of dry residuum, or 66·5 per cent. Now, by deducting the amount of sugar in the foregoing analysis, 40·12, from the amount of solid matter, we have 65·38;

* From destruction of an organic alkaline salt.

so that the accuracy of the analysis is confirmed, the difference between the results obtained in the two experiments being $66.5 - 65.38 = 1.12$.

Hence the difference in weight between the dry residua of two equal portions of diabetic urine, of which one has been fermented before evaporation, indicates precisely the amount of sugar, the carbonic acid escaping during the process of fermentation, and the alcohol being driven off by evaporation.

Wishing to determine precisely the effect of a pure animal diet upon the urine in diabetes, I provided food for Roberts during four consecutive days. Accordingly, he came to my house in the morning, and returned home at night. From my knowledge of the man, I can safely affirm that the following results are worthy of confidence.

He came, for the first time, in the morning, March 11th. During that day his diet consisted of beef-steak, strong beef-tea, eggs, and water flavoured with whiskey.

March 12th.—He took—

Breakfast:—Beef, 3 ozs.; beef-tea, 13 ozs. (avoiropois).

Dinner:—Beef, 6 ozs.; beef-tea, 26 ozs.; water 8 ozs., containing about a table-spoonful of whiskey.

Tea:—Beef, 5 ozs.; beef-tea, 13 ozs.; water, 8 ozs. containing about an ounce measure of whiskey.

In 24 hours, from last evening to the same time to-day, he passed 72 fluid ounces of urine, of which the greater part was voided in the night.

Characters.—Turbid. Colour, pale brown. Sp. gr. 1037; temp. 56° F. I estimated the sugar by fermenting 100 grains of urine over mercury in a graduated receiver, and measuring the carbonic acid evolved. The urea was ascertained in the usual manner with nitric acid, &c. the urine having been previously fermented.

1000 parts yielded	of sugar 37.3
	of urea 20.24.

March 13th.—

Breakfast:—Mutton, 5 ozs.; beef-tea, 24 ozs.

Dinner:—Ditto 9 ozs., a small quantity of fish, and water, flavoured with whiskey, 8 ozs.

Tea:—Beef, 5 ozs.; beef-tea, 9 ozs.; water flavoured as before, 8 ozs.

Complained of slight thirst. Spirits much improved. No stool during the last three days.

From 6 P.M. yesterday to the same time to-day, he passed 54 fluid ounces of urine, of which he voided 28 ounces in the night; of sp. gr. 1039°; temp. 56° F.

Characters.—Urine passed in the day. Colour, pale straw, lighter than that of yesterday. Copious flocculent sediment (urate of ammonia). Reaction acid. Sp. gr. 1036°; temp. 56° . I fermented 200 grains over mercury.

1000 parts yielded	of sugar 24.95
	of urea 31.18.

March 14th.—

Breakfast:—Beef, 6 ozs.; beef-tea, 14 ozs.

Lunch, 11 A.M.:—Beef-tea, 13 ozs.

Dinner:—Beef, 6 ozs.; water, as before, 8 ozs.

Tea:—Beef, 5 ozs.; 1 egg; milk, 15 grs.

Urine passed, in 24 hours, 68 fluid ounces, before the milk was taken. Sp. gr. of that passed during the day was 1038°; temp. 46° F. Characters similar to those of the preceding specimens. I fermented 200 grains over mercury.

1000 parts yielded	of sugar 34.35
	of urea 20.86.

I could never obtain crystallized sugar from any specimen of Roberts' urine. I evaporated one portion in vacuo over sulphuric acid, and left the residuum exposed to the atmosphere for a month, and yet no crystallization of sugar appeared.

The experiments last detailed confirm the results of M'Gregor, and justify the conclusion that in diabetes mellitus grape-sugar may be formed out of previously assimilated matter, or out of the protein series of compounds of the food. It will be observed, that, during the restriction of the patient to a purely animal diet the proportion of urea was increased; so that in accordance with the recent researches of Lehmann, a direct relation appears to exist between the nature of the diet and the proportion of urea in the urine. In extraordinary circumstances we can easily understand, by reference to formulæ, how a protein compound can supply

carbon for pulmonary oxidation, and yield grape-sugar and urea. Thus, 1 equivalent of protein, 52 of oxygen, and 4 equivalents of water, may be represented by 2 equivalents of grape-sugar, 3 of urea, and 18 of carbonic acid—
 $(C_{48} H_{36} N_6 O_{14}) + O_{52} + 4HO =$
 $2(C_{12} H_{14} O_{14}) + 3(C_2 N_2 H_4 O_2) + 18(CO_2)$

[To be continued.]

REPORT OF FATAL DISEASES AND MORBID APPEARANCES

OBSERVED IN THE POST-MORTEM EXAMINATIONS MADE AT ST. GEORGE'S HOSPITAL DURING THE YEAR 1843.

By HENRY LEE, Esq.

Formerly House-Surgeon to St. George's Hospital.

(For the London Medical Gazette.)

DURING the last few years a record has been kept of the morbid appearances observed in every patient who has died in St. George's Hospital. In the beginning of the year 1843, the task of noting these appearances was connected with a system of registration, by means of which the history of each patient with regard to the period of his admission, the result of the case, and any very remarkable circumstances connected with it, might in every instance be traced.

The number of cases admitted during the year amounted to three thousand one hundred and fifty-five. These, when classified under the heads of different diseases, are not sufficiently numerous to offer many points of statistical information, but will probably become valuable when added to the results of future years. As, however, in every case, the morbid appearances observed after death have been separately and carefully related, some account of the general results obtained may not be uninteresting. Although any attempt to give an analysis of the pathological changes in a number of cases, especially when such changes have taken place in the fluid parts of the body, must necessarily be very imperfect, yet the principal cause of death is generally sufficiently apparent. The following account will therefore refer to some of the most apparent causes of

death, and not to all the morbid appearances observed.

The value of this mode of reviewing a number of cases, too large to be retained separately in the mind, would be greatly increased, if, during succeeding years, a more complete history of the cases, including the treatment pursued, were added to the description of the morbid appearances.

The number of fatal cases which occurred at St. George's Hospital during the year amounted to two hundred and seventy-seven*, including thirty-six cases admitted for various accidents and external injuries. In two hundred and thirty-nine cases, the body was examined after death; and in thirty-one of these, death was the result of external violence. The following account is therefore taken from thirty-one cases in which death was the result of accident or external violence; and two hundred and eight in which it arose from natural causes.

CONSEQUENCES OF EXTERNAL VIOLENCE.

Compound fracture.—Of eighteen cases of compound fracture, which occurred during the year, eight proved fatal. In three instances, secondary abscesses formed, and death supervened between the twenty-second and thirty-third day. In one case, the synovial membrane of the knee-joint became distended with purulent fluid subsequent to an attack of erysipelas five months after the accident. Two of the cases were complicated, respectively, with fracture of the spine and of the pelvis. The patient, in one instance, at first refused to have the injured leg removed, and died of diffuse cellular inflammation after secondary amputation of the thigh. The remaining fatal case was one of compound fracture of the skull, in which both the *dura mater* and the brain were wounded. The average period at which death occurred, in the eight cases referred to, was thirty-four days. A more detailed account of these cases will probably be given when the number of cases becomes sufficiently large to afford points of statistical interest.

Simple fracture of the skull proved fatal in three instances.

Fracture of the vertebra was the cause of death in four cases, in all of

* Several of these were cases of advanced disease, in which the patients died shortly after admission.

which the spinal chord was found more or less softened opposite the seat of fracture. The softening, in one instance, had proceeded to such an extent that, when placed in water, one small band of medullary matter alone remained to connect the upper and lower portions of the chord. The surrounding vessels, in this instance, were only slightly congested. Extravasation of blood was found in the softened portions of the chord in two cases.

Fatal concussion of the brain occurred in two instances. In the first of these the trephine had been applied over a collection of purulent fluid between the dura mater and the bone. The cancellous structure of the bone was, after death, found filled with offensive purulent fluid, and suppuration had extensively involved the membranes of the brain. In the second case there was, besides the injury of the head, a fracture of the anterior part of the cricoid cartilage. The mucous membrane of the larynx, a little above the situation of the fracture, but below the chordæ vocales, was lacerated, and a probe might be passed freely through this aperture in the mucous membrane, between the broken portions of the cartilage. The cellular membrane around the fracture was distended with air, and from this point emphysema extended upwards into the neck*, and downwards into the anterior mediastinum.

Fracture of the pelvis occurred as the cause of death in three cases; and of the ribs, combined with laceration of the pleura, in four. Two instances presented themselves of rupture of the liver from external violence, and one of rupture of the heart. This last case occurred in a lad five years of age. The heart, externally, presented no mark of violence, with the exception of a circumscribed patch of extravasated blood beneath the *pericardium*, situated about the centre of the heart, and corresponding to the posterior attachment of the *septum*. Opposite to this point, the structure of the heart was broken down internally; so that a probe might be passed from either ventricle into the extravasation, and from one ventricle to the other, without opposition. External violence was also the cause of

rupture of the small intestine in one case, and of the kidney in another.

SCROFULOUS AFFECTIONS.

Of those examined, fifty-three died of phthisis, or other scrofulous affections. In fifty* of these cases the lungs were found affected with tubercles in various stages of development; and in forty, one or more vomicae presented themselves. No tubercular matter could be detected in the lungs in two cases: in one of these the pulmonary tissue appeared quite healthy, while in the other the lower portions of both lungs were occupied by numerous tortuous cavities, communicating with each other, and with the dilated bronchial tubes in the neighbourhood. These cavities, between which the structure of the lungs was compressed, were lined by a smooth lubricated membrane: they contained, together with bronchial tubes leading to them, a quantity of offensive, discoloured, purulent fluid.

In twenty-six of the fifty cases, the lungs had undergone some degree of condensation, independent of the deposition of tubercular matter.

In the great majority of cases the pleura was found adherent, and in thirteen instances presented recently effused lymph upon its surface.

Pneumothorax in consequence of ulceration of the pleura pulmonalis presented itself in five instances, in four of which suppuration of the pleura had taken place. Effusion of serum into the pleural cavity occurred in fourteen instances.

The kidneys were found diseased in twenty of the above cases. In nine of these they contained scrofulous deposit, and in four the pelvis of the kidney was coated with tubercular matter.

The liver was affected in thirteen, in seven of which it was simply enlarged, and in three it contained tubercular deposit.

Tubercular thickening of the peritoneum was noted in five cases.

Scrofulous abscesses formed in different large points in eight instances, of which four occurred in the hip, two in the knee, one in the elbow, and one in the wrist.

The brain.—Scrofulous tumors presented themselves in the brain in three instances; and in one a small tubercular deposit was found beneath the arach-

* During life, very considerable quantities of air had been forced, by the efforts of coughing, through the opening in the larynx, and the emphysema in the neck was so troublesome that several incisions were made to relieve it.

* In one case the lungs were not examined.

noid upon the pons varolii. A thick pulpy layer of scrofulous matter was also, in this case, found in contact with the posterior surfaces of the bodies of the cervical vertebræ. The posterior common ligament of the spine, and the transverse ligament of the atlas, were completely destroyed, with the exception of a very thin filament of the latter: this alone retained the odontoid process in its situation. The dura mater, in the upper part of the cervical region, was thickly coated upon its anterior surface with tubercular matter, a thick layer of which was continued from this situation upwards through the foramen magnum to the sella tursica. The bones in contact with this scrofulous deposit were all in a state of caries; and in the basilar process of the occipital bone an ulcerated opening existed, communicating with the upper part of the fauces.

Softening of the brain occurred in two instances, in one of which nearly the whole of one hemisphere was affected, the medullary substance being reduced, in some situations, to the consistence of cream.

A scrofulous abscess, not accompanied by any apparent alteration or increased vascularity of the surrounding cerebral substance, presented itself in one instance.

The only remaining case in which the brain was found diseased, in those who died of tubercular affections, was one in which the space at the base of the brain, between the commissure of the optic nerves and the pons varolii, was occupied by a thick layer of yellow gelatinous lymph. The deposit of this substance had taken place in the cells of the pia mater, by which it was conducted into the descending horns of the lateral ventricles, which were greatly distended with turbid serum.

The average age at which death occurred, in the above fifty-three cases, was twenty-seven years and a half.

CANCEROUS AND OTHER DISEASES USUALLY TERMED MALIGNANT.

Under this head are included twenty-six cases. The brain was affected in three instances. In the first of these a tumor, of a firm consistence, of a dark brown colour, and rather larger than an egg, was situated in the middle of the posterior lobe of the left hemisphere. The lateral ventricles, and especially the descending cornua, were much dis-

tended with fluid. A small oval tumor, of healthy cerebral substance, appeared immediately to the outside of the tractus opticus on each side, corresponding exactly to the lower portions of the descending cornua, and apparently produced by the fluid which they contained: these small projections compressed the optic nerves, and it is remarkable that in this case the patient has suffered from amaurosis, unaccompanied by any other apparent affection of the nervous system, for several months previous to his death. In a second case nearly the whole of the left hemisphere had become affected with malignant disease. It was in many places much softened, but the part corresponding to the squamous portion of the temporal bone had become converted into a tough reddish-brown fibrous substance, intimately connected with the dura mater. In this instance there was either no paralysis, or it existed in so slight a degree that no mention is made of it in the history of the case. In the third instance an extensive deposit of encephaloid matter occupied the right hemisphere of the brain. The diseased portion presented several extravasations of blood, the largest of which was the size of an almond. In this case severe and constant pain had for a long period been experienced on the right side of the head, when paralysis of the left side of the body, accompanied by temporary insensibility, suddenly made its appearance. The paralysis, in these cases of malignant disease of the cerebrum, appears to have been produced rather by some accidental occurrence during the course of the malignant growth, than by the disease itself.

In six cases the lungs were the seat of the disease, which, in five instances, consisted of encephaloid deposit. Of the six cases three occurred in conjunction with similar disease of the liver; and one was accompanied by disease of the thyroid gland. In this instance the natural structure of the gland had almost disappeared; the only remaining portion of it was a small part of the left lobe, which was intimately connected with the diseased structure. A large lobulated oval tumor extended from the thyroid cartilage to the sternum, projecting laterally beyond the sterno-cleido-mastoid muscle. Upon the inner side of the tumor was a large ulcerated cavity communicating with

the anterior part of the œsophagus, and also with the upper part of the trachea. The tumor presented internally the genuine characters of scirrhus.

In one instance the great intestine was the seat of the disease. The cœcum, together with a portion of the ascending colon, was greatly thickened, and presented, upon its internal surface, numerous irregular patches of ulceration: each ulcer was surrounded by an areola of inflammation, and presented upon its surface an unorganized white layer,

firmly attached, and resembling a superficial slough. In the thickened parietes of the bowel there existed numerous small rounded tumors: these at first appeared hard, but when cut into were found to consist of a brownish semifluid substance. The absorbent glands in the meso-colon of the right side were similarly affected.

The accompanying table indicates the organs affected, and the various parts simultaneously diseased in the different cases.

TABLE SHEWING THE PARTS AFFECTED IN TWENTY-SIX CASES OF MALIGNANT DISEASE.

	No.	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	23	24	25	26	In 3 cases

— Indicates that the part mentioned in the margin was the seat of the disease in the case under the number of which it is placed.

* Mesenteric glands.

In five cases the disease was confined to one situation. The parts thus affected were the pyloric orifice of the stomach, the rectum, the pleura, the brain, and the cellular tissue between the larynx and pharynx. The average ages at which death occurred was 45 years.

[To be continued.]

FUNCTIONS OF THE TRUE SPINAL SYSTEM.

By ———.

(For the London Medical Gazette.)

WITH the hope of obtaining further information on some difficult points in connection with the true spinal system, I take the opportunity afforded by the pages of the LONDON MEDICAL GAZETTE, to make the following observations.

It has occurred to me, in thinking on the reflex symptoms of the true spinal system that the explanations given by Dr. M. Hall are in some degree defective, and lead us to wrong conclusions in pathology.

It would be altogether impossible within the compass of a short paper to examine this question in all its bearings. I will, therefore, confine my notice to a few points only.

The curious reflex phenomena which Dr. Hall has described as occurring in paralysed limbs, are no doubt familiar to most of your readers. In some instances, slight irritation of the palsied extremity, will excite it to involuntary twitchings and contractions; in others, these symptoms cannot be produced. Sometimes the limb is found permanently rigid and contracted, at others it is relaxed and extended. Dr. Hall explains this circumstance by supposing that the convulsive motion of the limb, or its rigid contractions, arise from the controlling influence of the brain being lost, and that the muscular movements are abandoned as it were to the true spinal system. He further concludes, when the reflex functions cannot be excited, that the true spinal system is itself the seat of morbid action. My own observations lead me to suspect that Dr. Hall's conclusions are erroneous: that true reflex functions when exhibited shew, *not* that the cerebral influence is destroyed, but that it

is merely perverted, and that when the brain ceases to have all influence over the palsied parts, the reflex functions cannot be excited, although there is no reason to suppose any alteration in the condition of the spinal marrow.

In the first place I will refer to cases where the reflex phenomena were present so long as the paralysis was incomplete; so long, in fact, as some cerebral influence was retained over the palsied limbs; while as soon as this influence ceased, and the paralysis was complete, the reflex functions were at the same moment rendered inactive.

In Andral's Clinique Médicale, Vol. iii. p. 14, a case of incomplete paralysis of the right side is detailed, in which the sensation of the palsied parts is retained. The paralysed limbs were spasmodically contracted.

Here there is the reflex function in action whilst the sensation of the parts remains. The functions of the cerebrum were not destroyed; a certain degree of influence over the palsied limb was still exercised by the brain. But mark what follows: the sensation is suddenly lost, and at the same moment the contracted limbs relax; the reflex phenomena cease. Paralysis of sense and motion is complete. The moment that the loss of sensation in the affected parts announces that the cerebral functions are destroyed in it, that moment the true spinal phenomena are equally removed.

I have many similar cases, but I will not trouble you with any allusion to them now, but proceed to other facts leading to precisely the same conclusion.

Not unfrequently cases are met with where one side is completely paralytic, while on the other side one or both limbs are contracted. Now, according to Dr. Hall's theory, the true spinal system exercises its function over the contracted limb, the brain having abandoned the parts affected to the reflex action; whilst on the side where the palsy is complete the true spinal system is itself in fault. But if any faith is to be placed in reasoning founded on morbid anatomy, it would appear that the contraction arises from a minor degree of disease in the brain itself than that which produces complete paralysis. I will allude to a case in *Lallemand*, vol. 1, page 15, to illustrate this. The patient had complete hemi-

plegia of the left side, with a flaccid state of the muscles. The *right* limbs, on the contrary, were permanently flexed, so that the toe touched the nates, and the thumb was immovably applied to the shoulder.

In a post-mortem examination, disease was found in both hemispheres of the brain; but on the right side it was much more advanced than on the left.

This case (to which I might add many others) shews that it is the brain itself which regulates the reflex phenomena, a minor degree of disease in that organ producing perverted muscular action, a large amount of disease occasioning the complete destruction of the reflex functions.

In many apoplectic cases the patient is suddenly deprived of sense and voluntary motion, or with complete hemiplegia, no reflex phenomena being apparent in the affected limbs; but after a certain period the limbs begin to contract, and afterwards remain in a rigid state.

Now this seems capable of explanation on two conditions; first, that when the effects of the shock on the brain have somewhat subsided, its functions become gradually, but still imperfectly, restored. The consequence is that the limbs become more or less contracted. In other cases the same train of symptoms might be caused by a healthy process going on within the cranium after an apoplectic seizure.

In Andral there is a case where the patient was suddenly seized with complete left hemiplegia. The limbs were flaccid, and remained so for a period; afterwards they began gradually to contract, and became rigid. Death, however, occurred; and, upon examination, an organised membrane was found completely surrounding the apoplectic cavity, shewing that a healing process had commenced in it.

These remarks will be sufficient to call attention to the subject, if it is worthy of notice. I forbear to allude now to other circumstances, and especially to the experiments made by Dr. Hall on living animals. Some of these I may hereafter shew to be capable of explanation in accordance with the views now advanced.

MR. LEY ON CANNABIS INDICA.

To the Editor of the Medical Gazette.

SIR,

IN Mr. Solly's clinical lecture on Tetanus, published in this day's *GAZETTE*, he relates the history of a case in which he employed the Indian hemp. Admitting "that the spasms began to abate soon after its administration," he says, "it is very doubtful if the Indian hemp had any share in the relief of the symptoms." The effects produced, if any, show that the preparation used was either inert, or insufficient in quantity. The promised and marked results were not produced,—relaxation of the muscles was not effected. Although, therefore, sleep in short naps does appear to have been obtained, probably with much benefit, yet the medicine as administered was inefficient. Between ten o'clock p.m. December 29, and twelve at night, December 30, a period of 28 hours, the patient took 350 minims of the tincture, which would contain of Mr. Squire's tincture, about 30 grains of the resin, which, as most readily procured, was probably the medicine used on this occasion. It is unfortunate, but true, that the Gunjah was deteriorated by age in this case, before it was appropriated for use as medicine. When Dr. Clendinning's paper on Cannabis Indica was read at the Medico-Chirurgical Society, he said that he had used the tincture prepared by Mr. Squire, but that he had also used another more recent preparation, made at Calcutta, with which I had provided him, which appeared, by comparisons repeated on several persons, to be certainly *five times the strength* of the other. I need not say, that in the treatment of tetanus, unless the medicine used is of the *best quality*, the efficacy of the remedy is not fairly tried.

Had Mr. Solly noticed a case which I sent to the Provincial Journal of the 5th of August last, he would have been struck with two coincidences: first, the apparent benefit of the remedy when first administered; second, the great inconvenience of the tincture as the mode of administration. A third point, the comparative efficacy of two different preparations of hemp, is of even more importance.

I have recently had an opportunity of witnessing the effects of different preparations of the Gunjah on a lady who suffers from tetanic spasms in consequence of diseased spine. When she first took the remedy it was an extract, prepared at Calcutta: it was attended with perfect success when no more than 5 or 7 grains had been taken. She has since that tried four or five preparations of the medicine, apparently deteriorated by age, without relief, in doses of 30 or 40 grains. On a late occasion, however, on taking a more recent preparation, it was again followed by signal relief.

Mr. Squire has now a preparation sent from Calcutta by overland mail; apparently as recent as any we have received. I have seen that its effects in producing sleep are very powerful in doses of one grain.

I am, sir,
Your obedient servant,
WILLIAM LEY.

Crawford Street, April 13, 1844.

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

Guy's Hospital Reports. 2d Series, No. 3. April 1844.

THESE Reports were commenced in 1835, for the laudable purpose "of recording the many valuable facts which so extensive an institution as Guy's Hospital presented, and of rendering them available to those members of the profession who had not themselves had the opportunity of witnessing them." These Reports regularly appeared for seven years, and comprise a series of monographs by its medical officers, which are extensively illustrated by cases that have occurred in the institution, and, where necessary, by plates also. A New Series commenced with the April number of last year, in which it was proposed, in addition to such treatises, "to illustrate the different classes of disease by the aid of series of reports collected within the walls of the hospital, and furnished by the books of the Clinical Society, and also by the publication of anomalous cases derived from the same sources." It seems necessary to add, that the Clinical

Society, which, to the honour of the students, originated among themselves, consists of an organised body of reporters, taken from among the more advanced pupils, who divide the hospital into ten departments—four exclusively medical, four exclusively surgical, one mixed, and one obstetrical—in order to secure an account of every patient admitted. About thirty reporters suffice; and only so much time is required from each student as every one ought, at the advanced period of his pupilage when he becomes eligible into the Society, to devote to the practical study of medicine and surgery. There can be no better preparation than this for the proper discharge of those duties which, in the pursuance of his profession, must ultimately devolve upon every practitioner. A weekly meeting is also held in a room assigned by the Hospital, where all the cases admitted since the previous meeting are mentioned, the inspections after death and the operations performed during the week are detailed, and any subject of interest in the wards generally noticed; so that this assembly forms the centre of all the clinical information of the hospital.

As an authorised record of hospital cases on an extensive scale, the New Series presents higher claims to notice in detail than the former. The present number of the Reports contains five "papers" and two "reports," of which we shall proceed to give some account. In the first paper Dr. Lever details nine cases of "pelvic inflammation with abscess occurring after delivery." This disease, he informs us, is seldom noticed by systematic writers, but appears to have been known to Levret, William Hunter, and Deleurye; and has been particularly described in recent times as "secondary inflammation" by Dr. Kennedy, as "chronic inflammation of the uterine appendages after parturition" by Dr. Doherty, as "inflammation and abscess of the uterine appendages" by Dr. Churchill, and best of all, perhaps, by Professor Martin, jun., of Montpellier, in a monograph entitled "*Des Dépôts des annexes de la matrice qui surviennent à la suite des couches.*"

Dr. Lever is unable to determine whether the inflammation commences in the uterine appendages properly so called, or in the cellular tissue seated between their peritoneal covering and

the pelvic fascia. The channels by which the matter usually finds its exit—the abdominal wall near the round ligament, the vagina, or the rectum—distinctly prove that the cellular tissue of the pelvis is involved; and this has been confirmed by examination after death in a woman who died of phthisis (eighth case) some months after recovering from this affection.

"In the treatment of this latent (subacute and often obscure, we should have said) inflammation, heroic measures are not required, as it usually occurs in persons whose constitutional powers are much depressed, and demand mild and constitutional treatment." Where it proceeds to suppuration, and fluctuation can be distinctly felt, Dr. Lever advises that the abscess should be opened. The nine cases recovered.

Mr. Alfred S. Taylor, in the second paper, reports a case of poisoning by corrosive sublimate, and another by paregoric, replete with matters important to the analytical chemist and medical jurist.

In the third, Dr. Hughes and Mr. Cock severally discuss the mode of performing paracentesis thoracis, and its value as a means of mitigating suffering and curing "thoracic effusions." The details of eleven cases, and a table of twenty recent and hitherto unpublished cases of the operation, with the results, are appended, in order to present a fair estimate of its consequences.

From Dr. Hughes's remarks, we learn that, till within the last four or five years, this operation had been rarely employed in the hospital; but within that period it has been resorted to between twenty and thirty times, or perhaps more frequently; for exact records have not, in all instances, been preserved. "In several of these cases fluid has been drawn off, with the apparent effect of facilitating and hastening the cure. An earlier expansion of the lung, and the decrease or prevention of deformity of the chest, have been the result. In other instances the operation has been resorted to simply for the purpose of affording temporary relief. For hydropericardium, and effusion of blood into the thorax, Dr. Hughes has never seen the operation performed; but in pneumothorax, hydrothorax, and empyema or chronic pleuritic effusion, it is practised

with one of three objects: first, the direct cure; second, the relief of distressing symptoms; and third, facilitating the cure by other means. For the conditions of its employment in pneumothorax, our readers are referred to Dr. Hughes' essay on that affection, in the *MEDICAL GAZETTE* for January 1844. Most modern pathologists will agree with Dr. Hughes, that they "are not practically conversant with any effusion of water into the pleura independently either of inflammation of that membrane or of obstruction to the circulation in the heart, lungs, or mediastinum, excepting that which, in many cases, occurs a few hours before death, or is the consequence of exudation after that event." Tapping in hydrothorax, therefore, can only consistently be employed as a means of temporary relief, and of "affording a more extended period, under more favourable circumstances, for applying remedies for the removal or diminution of the original malady." "Increasing dyspnoea and orthopnoea, with a progressive dulness on percussion on one or both sides of the chest, which varies in situation according to the position of the patient, and which is found not to be under the control of other remedies," are the indications stated for the employment of paracentesis in hydrothorax.

In discussing the employment of paracentesis in chronic pleuritic effusion, and in empyema, the more immediate object of his paper, Dr. Hughes refers to, and quotes, his observations appended to a case of empyema in the *MEDICAL GAZETTE* of June 1839. He believes the distinction there drawn "between empyema, properly so called, and chronic pleuritic effusion, to be worthy of more attention than it has received. The cure, in the one case, when the lung is thickly coated by albuminous matter, permanently bound down by adhesions, and consequently incapable of expansion, can only be effected by the slow process of contraction of the side, and curvature of the spine, assisted by the gradual enlargement of the lung on the opposite side. It is likely, therefore, to be hastened only by the occasional withdrawal of small quantities of the fluid. When, on the contrary, as in the other case, the effusion has recently occurred, and, by the aid of the explorer, is proved

not to be purulent, it appears to be a legitimate object of treatment to prevent, if possible, such continued compression, and the formation of such dense pleuritic coating of the lung, as may interfere with its capability of future expansion, and to obviate the necessity of waiting for the tardy process of absorption, contraction, and distortion." The withdrawal of a certain portion of the fluid will afford space for the still expansible lung, and become an important adjunct to the other means of cure. Even in diseases necessarily fatal, as phthisis, suppuration of the lung, or mesenteric disease, when the dyspnoea and general distress are dependent upon fluid accumulated in the pleura, these symptoms will be greatly relieved, though no permanent cure can be effected by the operation.

Dr. Hughes is perfectly aware that Drs. Stokes and Hope, and many others, have published or referred to a great number of cases in which empyema, or chronic pleuritic effusion, so called, have been cured without operation. He has himself seen many such cures, and effected several; but he nevertheless believes that the occasional abstraction of a small quantity of fluid will accelerate and materially contribute to the cure, and that its adoption is especially desirable where the general health, state of constitution, or other circumstances, render a prolonged purely medical treatment injurious or undesirable.

Many practical remarks on the diagnosis follow; but we must pass on to the observations of Mr. Cock, who states that "the certainty of diagnosis which auscultation affords has reduced the operation from a hazardous and uncertain undertaking to one which is practicable by any surgeon of ordinary manual dexterity, and has rendered it available as an early remedial measure, instead of, as formerly, a desperate remedy, or a last resource." The presence of the fluid is not indicated by external physical signs, as separation of the ribs, bulging of the intercostal muscles, and depression of the diaphragm, till the lungs, the weakest structure, have been compressed into the smallest possible space, and probably rendered for ever impermeable to the ingress of air. These signs have in no case existed where Mr. Cock has been called upon to tap the chest. He regards the preternatural bulging and

increased volume, when measured and compared with the other side, as "owing to the chest remaining in a state simulating that of permanent inspiration, and not, as erroneously ascribed, to a general expansion of the thoracic walls from the pressure of the fluid accumulated within:" the chest is, in fact, shortened in its dimensions from above to below, while it is expanded in its antero-posterior and lateral dimensions. In every case the existence of the fluid has been most clearly indicated at the lateral and posterior part of the chest, in a position somewhat central between the upper and lower boundaries; and he has "tapped below the angle of the scapula between either the seventh and eighth, or the eighth and ninth ribs, and at a point distant from one to three inches from the angles of these bones."

Previously to tapping he explores the chest with the instrument contrived by Dr. Babington for that purpose, which he greatly prefers to the grooved needle. "It consists of a needle contained in the smallest sized canula; this is passed between the ribs where the fluid is suspected; the needle is withdrawn, and the escape of fluid from the tube at once indicates the existence and the nature of the abnormal secretion. A farther investigation, as to the size and direction of the cavity, may also be obtained by introducing a fine silver probe through the canula."

The trochar and canula which Mr. Cock finds best adapted for the tapping itself is about $\frac{1}{4}$ th of an inch in diameter, and about two inches in length, exclusive of the handle. This ensures a gradual evacuation of the fluid, and with proper precautions avoids the admission of air; air should always be sedulously excluded, from its tendency to give rise to a fresh attack of unhealthy inflammation in the walls of the cavity, and a fresh effusion of lymph on their surfaces. None of the instruments contrived to allow the escape of the fluid, and prevent the introduction of the air, have been found so well adapted to the purpose as the small trochar and canula here recommended. Figures of the trochar and explorator are given. The steps and precautions necessary for the success of the operation are minutely described: we have only space for the following remarks: "When a continuous stream can no longer be obtained by a more dependent position,

or by pressure made on the lower part of the chest by the hands of an assistant, the canula should be immediately withdrawn, and the opening closed while the chest is yet in the grasp of the assistant; for if he relax the pressure while the communication with the pleural cavity is still open, air will infallibly rush in. Independently of the direct injury which its presence may occasion, it would impede the restoration of permeability to the compressed lung, by preventing that tendency to a vacuum within, which the resiliency of the parietes will occasion when the pressure is withdrawn. The stream of fluid should never be allowed to become completely interrupted during the effort of inspiration, and the admission of the slightest quantity of air, as indicated by a peculiar sucking noise, is the signal for the prompt withdrawal of the canula. The operation is so simple, and so little painful, that it may be repeated whenever it seems advisable.

"Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO

ROYAL COLLEGE OF SURGEONS OF IRELAND,

THEIR LICENTIATES, AND THE MEMBERS OF
THE MEDICAL PROFESSION GENERALLY,
SETTLED IN IRELAND.

IN a statement which was addressed to us very recently by the Registrar of the Royal College of Surgeons of Ireland, explanatory of the supplemental charter lately granted to the College by her Majesty, it is stated that the Government "took advantage of the opportunity to enable the College to constitute itself into a really national body, such as should be fitted to represent and to protect the interests of the entire surgical profession in Ireland, by granting the power to the council for one year of incorporating as fellows such practitioners as they may think entitled to the honour by their

personal respectability and professional rank."

The Council of the Irish College therefore notify to practitioners in surgery desirous of being incorporated into the College, that they will receive applications to that effect until the 10th day of January, 1845.

Now it strikes us, that the course thus pursued by the Royal Irish College of Surgeons is open and honourable to themselves, respectful and considerate to the members of the medical profession settled within the limits of their jurisdiction—very few of whom, comparatively, have any connection with the College.

Let us see "the conditions according to which applications are to be made for reception among the number of Fellows of the Royal College of Surgeons of Ireland." These are few, and, with one exception, we conceive perfectly fair and proper; viz.:—

"1. That candidates shall lay before the Council evidence of their being qualified practitioners, or commissioned medical officers in the Army, Navy, or East India Company's service, of not less than seven years standing.

"2. That the applications of such candidates shall be supported by the recommendation of at least three Fellows of the College.

"3. That candidates shall state to the Council their willingness, should they be admitted Fellows, to make and subscribe the following declaration and affirmation as required by the Charter.

"I. A. B., do solemnly and sincerely declare that I am twenty-five years of age and upwards, and that I will observe and be obedient to the statutes, bye laws, and ordinances of the Royal College of Surgeons in Ireland, and that I will, to the utmost of my power, endeavour to promote the reputation, honour, and dignity of the said College, and that I do not now practise the business or profession of an apothecary, or druggist, or indirectly sell drugs or medicines, and that I will not, so long as I shall be Fellow of the said College, practise such business or profession.

"4. That the following fees shall be payable to the College by prac-

tioners who may be incorporated as Fellows :” which, as only of individual interest, we omit.”

The sole difficulty we perceive in the above conditions is that which has reference to the renunciation of the business of the apothecary ; by which we presume it is understood that no man shall be eligible as a Fellow, who has a surgery, however private, from whence he supplies his own patients, and them alone, with medicines.

Certainly we should like to see the profession of medicine in all its branches separated from the traffic in drugs and chemicals, and even from the business of privately furnishing medicines ; but such a condition as this renders the whole of the proffered boon nugatory in the present constitution of the profession ; and we venture to maintain that it is framed upon a false principle, and that as a general rule it is not defensible. The general practitioner, *i. e.* the member of a Royal College of Surgeons, and licentiate of an Apothecaries’ Company, who supplies his patients with the medicine they require, is the representative of the medical profession at large, in the eye of the community ; and he is so under the sanction of the law : he could not exercise his calling according to the wants of society without a license from the Apothecaries’ Company : he was liable to prosecution if he did.

Now it is obviously absurd to frame new laws that shall not meet the state of things created by old enactments ? If I have been compelled upon a particular line of life by existing laws, shall I be made obnoxious to degradation,—to moral punishment, the worst punishment of all to bear, for having obeyed them ? The thing cannot, must not be. And then, we would ask whether there was in fact aught disreputable in any man of liberal professional education sending to his patients from his own house the medicines which

he had himself prescribed ? Such a man is no *petty trader*, no *dealer* in drugs or medicines, and it were both unjust and impolitic publicly to cast a slur upon him, which in private is unrecognized. Everywhere physicians and surgeons have general practitioners at their houses as their guests, and among the number of their intimate friends ; these general practitioners in their turn entertain, and are on the most familiar terms, with physicians and surgeons. It is only in the three capital cities of the three divisions of Great Britain that any such person as a *pure* surgeon exists ; and in one of these his appearance is even of very recent date. In the city of Edinburgh, no more than twenty years ago, every Member of the Royal College of Surgeons had a private surgery, and supplied his own patients with their medicines. From the ranks of these gentlemen, however, were elected the surgeons to the Royal Infirmary, who did all the capital operations, and were in every respect upon a par with our metropolitan hospital surgeons. Benjamin Bell, whose *System of Surgery*, and book on Wounds, were for half a century and more classics not only in this country, but over the whole continent of Europe, supplied his patients with their medicines. John Bell, the most brilliant surgeon of his age, the ablest writer of his day, did the same ; and so did all his contemporaries and successors down to the time of Mr. Liston, who was the first Edinburgh surgeon who had no surgery in his house. The surgeons to all our provincial hospitals are general practitioners. The late Mr. Hey, of Leeds, supplied his patients with the medicines they required ; the present Mr. Hey, of Leeds, does so ; and so, to the best of our knowledge and belief, do all our extra-metropolitan surgeons without exception.

Having said so much, we think we have said enough to satisfy every un-

prejudiced mind, that the general practitioner, with his private surgery, and whose apprentice or dispenser compounds his prescription, is every whit as good and as respectable a man as he whose recipe goes to the next chemist and druggist's shop: for this is the whole and sole difference between them in fact. If the matured physician or surgeon, with his grey hairs and failing teeth, and fast decaying powers, feels that he is not paid with less than the customary fee, has he forgotten that when he was a younger man, unless fortune had been all the kinder to him, he was not so scrupulous in reckoning the number of his visits between the receipt of one fee and that of another? But many of the general practitioners of the present day make a regular, moderate charge for their visits, and supply the requisite medicine gratis: they do, in fact, what every expectant young surgeon and physician is compelled to do in the beginning of his career.

Such distinctions as are essayed to be kept up by the conditions annexed to eligibility to their fellowship by the Council of the Royal College of Surgeons in Ireland, are absurd in themselves, indefensible in principle, and highly injurious in effect; they do the whole profession incalculable mischief. By making the fellowship inaccessible to the general practitioner, *whom the wants of society have made, and will still continue to make*, the vast majority of medical practitioners, the representatives of the medical profession in the eye of the public at large, are virtually degraded, by being declared unworthy of assumption into the highest grade of the branch which they practise, and there can be no question of the deteriorating influence which such a state of things must have upon their intellectual and moral state, as a reflex of this, upon their social position, and, as a final effect of all, upon the estimation in which the entire body of the medical

profession is held with the world at large.

It were a poor vanity that should make circumstance or accident a ground for lording it over many gentlemen with whom we have the pleasure of being upon terms of intimate friendship, and who practise generally in London. If these gentlemen do not hold themselves in readiness at a moment's notice to undertake difficult and delicate operations, it is only because they have been accustomed to have a Cooper and a Brodie at their elbow, in the daily habit of using the knife;—their education and their knowledge still fit them to do all that any professional man can be required to do; their conduct in life makes them beloved and respected wherever they come. We are therefore sincerely happy, on referring to the charter of the Royal College of Surgeons of England, to observe that elevation to the fellowship there is clogged with no such condition as that which is grafted upon the supplementary charter to the Irish College. The Fellows may agree among themselves that they will not make councillors of those who practise generally; this is matter of comparatively private arrangement, it is no public stigma.—The time and attention that must necessarily be given, in these days, to the business of the Councillor's office, would ill assort, indeed, with the laborious duties of the general practitioner. But he surely is not disqualified, either by acquirement or position, from exercising the rights of elector either to the Fellowship or the Council. Let traffickers in drugs, and petty retailers of medicines, with their red and blue bottles, and gas-lit open shops, be excluded by all means from what ought to be held the *professional grade* in the Royal College of Surgeons, whether of Ireland or of England; but let not the private supply of medicine prescribed by the individual himself be any bar to his admission to the worthiest place

TO OUR FRIENDS.

WE own that we lend our space to accounts of personal differences, to disputes about priority, &c. between members of the profession, reluctantly. It is sometimes just and necessary to do so nevertheless, and it is done. We would suggest, however, that points of extreme interest to the parties concerned, are rarely so to the profession at large; that differences which look like mountains vast and gulphs impassable to the individual, are commonly mere mole-hills and gutters in the eyes of the world at large. The world wants light; it is each man's part to do his best to bring it: he may fairly trust the world with giving him credit for his exertions and successful efforts. If any other man attempt to strip him of his plumes, the thievish daw is soon detected, and turned out naked not only of all the feathers he had *borrowed*, but often of those that grew from his own flesh. In the column that is occupied by a letter from Dr. A. or Mr. B., complaining that Mr. C. or Dr. D. had not done him justice, we could often put an interesting case, or pack a piece of positive or more speculative information, that might prove as seed cast on the waters, or trusted to the winds, but destined by and by to find a congenial spot in which to take root and attain maturity, producing leaves and flowers and fruit.

These hints we throw out to some of our friends whose countenance we prize, whose support is needful to us, but whose differences and *reclamations*, as the French call them, we deprecate. They will serve as acknowledgments also of several letters which we shall keep safe in our drawer, unless we hear more particularly from their writers.

ROYAL MEDICAL & CHIRURGICAL SOCIETY.

Tuesday, April 23, 1844.

THE PRESIDENT IN THE CHAIR.

On Paracentesis Thoracis as a curative measure in Empyema and Inflammatory Hydrothorax. By HAMILTON ROE, M.D. Physician to the Westminster Hospital.

THE author commenced his paper by alluding to the very generally received opinion of the uselessness of paracentesis thoracis as a curative measure in the treatment of pleuritic effusions, as founded upon the supposed facts, that reaccumulation of fluid necessarily takes place after its withdrawal by the ope-

ration; that the frequent repetition of tapping subsequently demanded in those cases in which life had been prolonged by it, was only sufficient for the alleviation of certain urgent symptoms; and lastly, that recorded experience is completely opposed to the employment of the operation. His own experience had induced the author to dissent from these opinions, and a careful examination of the cases recorded by various writers during a period of thirty years had supported him in the correctness of the results at which he had arrived. Of 39 cases recorded in the British medical journals between the years 1812 and 1842 (a period selected as that in which an acquaintance with auscultation had rendered the diagnosis more accurate), in all of which paracentesis had been had recourse to, he had found that eleven only died. Twenty-four cases had occurred to himself; and the chief object of the author was to prove, from the results he had obtained, that the operation is as free from danger as any other performed upon the human body; that most of the evil consequences supposed to attend it are far more imaginary than real; that it is commonly successful when employed at an early stage of either empyema or inflammatory hydrothorax, and the common cause of failure is to be found in the late period at which it is alone regarded as admissible.

The author next proceeds to notice at length the objections of certain writers to the treatment of empyema by operation, and opposes the opinion that the ultimate removal of pleuritic effusion must depend upon the action of the absorbents, and observes, "that the proper function of the absorbents is to carry off the ordinary healthy secretion, but not a diseased one; that their power may be sufficient to take up the quantity usually secreted, and yet wholly unequal to take up many pints added to it;" and that it is at least very probable that the action of the absorbents becomes paralysed partly by the over-distension of the membrane in which they are situated, and partly by the general prostration of strength produced by the great suffering, and the disturbance which the other functions undergo from the pressure upon vital organs. These views were supported by a case of inflammatory hydrothorax, in which the withdrawal of a small quantity of fluid from the chest was sufficient to lessen the mechanical pressure upon the absorbent vessels, and thus to enable them to reassume their healthy action, and by which the great bulk of the fluid was subsequently removed.

With reference to the supposed dangers of the operation, the author had been unable to find one case on record in which mischievous results have occurred. In his own practice no precautions had been employed to prevent the admission of air into the

pleural cavity, but no bad results had followed; and even in one case (the only example of the kind) in which the air failed to be absorbed with the rapidity commonly observed, it had been readily withdrawn by means of a syringe, the wound made in tapping the chest having been healed. But although the accidental admission of air at the time of the operation was never productive of bad effects, yet its continued entrance, in those cases in which a fistulous opening had been made into the pleura, had very commonly been followed by mischievous results: the author was therefore strongly in favour of the complete removal of the fluid, and the immediate closing of the aperture. Although it was difficult to determine what length of time might, without danger, be allowed for the exhibition of internal remedies, yet, from his own experience, the author was induced to believe that, in the general class of cases, three weeks is the longest period that can with safety be permitted to elapse before the withdrawal of the fluid. In none of his own cases had complete restoration of the lung resulted after it had been subjected to the pressure of pleuritic effusion for six weeks. It was important to understand rightly the exact state understood by the term "cured empyema," much of the difference of opinion relative to the propriety of tapping the chest depending upon the varied manner in which such expression is employed. Thus, in the posthumous essay of Dr. Hope, a long list of cases of empyema are recorded, in which the continued action of mercury was followed by "cure." In the essay in question, however, it is not stated that, in any one case, the lung had been restored to its healthy condition. By the early employment of paracentesis, those changes in the pulmonary tissue by which its expansibility is destroyed, are prevented; and thus not only is the removal of the pleuritic effusion effected, but the lung also restored to the full performance of its function.

The author next describes at length the morbid changes produced in the pleura by the long continuance of purulent collections, more particularly alluding to the manner in which the pleural sac becomes ultimately obliterated in chronic cases of empyema in which the effusion has been very slowly removed, and at a late period. As one of the secondary effects, he had also observed that tubercular disease of the opposite lung not unfrequently occurs in old cases of empyema. Amongst the several changes produced in the lung during the existence of pleuritic effusion, the most important were those by which it was rendered subsequently incapable of expansion. In old cases of hydrothorax the author had observed such effects to result from condensation of the pulmonary tissue, which was often so com-

plete as to prevent even partial expansion by the artificial introduction of air. In the cases in which purulent secretion had resulted, it had been frequently found that the pleura had become wholly altered in character; in some cases adherent to the parietes of the chest, in others greatly thickened and contracted, and so binding down and compressing the lung as to render its restoration impossible.

Twenty-four cases had occurred to the author, which had been treated by paracentesis thoracis; of these eighteen recovered, and six died. Nine of them were cases of purulent effusion, of which eight recovered, and one died. Thirteen were cases of inflammatory hydrothorax, of which nine recovered, and four died. One was a case of hydrothorax dependent upon cardiac disease, in which relief was afforded by the operation, and the remaining case was one of pneumothorax, having a fatal termination.

In conclusion, the author remarked on the comparative value of certain physical signs, alluding to one of them, namely, the distension of the intercostals, as a differential sign, serving to mark the character rather than the quantity of the contained fluid; he had repeatedly found that retraction of the intercostals had existed with a very large amount of pleuritic effusion, and on the other hand, that very distinct bulging of those spaces had been present with a very small quantity of fluid. In the former class of cases the fluid had been serous, in the latter purulent, and he was disposed to adopt the opinion of Dr. Stokes, and of some of the older writers, who believe that the projection of the intercostals depends upon the purulent character of the effusion. The inability of patients affected with pleuritic effusion to lie upon the healthy side, had not been observed to accord with the opinion commonly expressed in systematic works; but that the contrary rule obtained in nearly one half of the cases. It was somewhat remarkable that the disease more commonly existed on the left side of the chest, and of the twenty-four cases adduced by the author, the ratio had been as two and a half to one.

Account of a case of Empyema which recovered after repeated punctures of the pleural sac. By THEOPHILUS THOMPSON, M.D., Visiting Physician to the Hospital for Consumption and Diseases of the Chest.

IN the summer of 1843, Dr. Thompson visited, with Mr. Roberts, of Great Coram Street, a little boy, between five and six years of age, who had suffered for two months from febrile symptoms.

On examining the chest, conclusive indications were observed of purulent effusion in the right side, and the operation of paracentesis thoracis was performed on the 27th of June. The puncture was made through the

fourth intercostal space, and fourteen ounces of pus were withdrawn; various precautions being adopted to prevent as much as possible the access of air. On the 30th June the operation was repeated, and about a pint of matter withdrawn. The relief obtained, although very considerable, proved only temporary; notwithstanding the use of appropriate remedies, the accumulation was renewed, and on the 10th of July the operation was performed for the third time, twenty ounces of pus being removed. After the performance of the fourth operation on the 21st of July, when twenty-two ounces of thick but not fetid matter were removed, the boy improved in strength, and the excess in girth of the right side of the chest over the left was materially reduced. On the 28th of July, the puncture which had been for some days perfectly healed, opened spontaneously, and within twenty-four hours gave exit to about four ounces of pus. After three days the discharge ceased, but above the seat of the two last punctures a swelling was found about two inches in length, at the posterior part of which, an aperture discharging matter appeared. On the 16th of August both openings were discharging, the anterior spontaneously, the posterior when pressed. The local symptoms gradually became more favourable, and the general health improved, so that in September the boy was able to walk out. The right side of the chest contracted, and in the month of November was an inch and a half less than the left in circumference. A partial healing of the aperture being followed by some aggravation of the symptoms, it was determined to attempt the gradual emptying of the sac and approximation of its sides. This object was successfully obtained by means of plugs made of sponge firmly tied with pack thread, and saturated with wax. Matter which was to the last inoffensive was thus repeatedly removed from the cavity. The opening healed about the end of January, and the boy has since remained perfectly well.

The author remarks, that although *serous effusion* into the pleural sac is frequently removed with little assistance from medical treatment, yet that in cases of considerable *purulent* effusion there is little hope of relief without an operation, which in most instances should be performed *early*, without losing time, and hazarding strength, by the use of mercury and diuretics. He argues that puncture of the thorax involves no circumstance of peculiar hazard, provided suitable precautions be adopted. Amongst these precautions he urges the expediency of repeating the operation in preference to removing a large quantity of pus at once, and especially insists on the conclusive evidence which recorded cases afford, that the practice of leaving a canula in the wound is

highly detrimental, in consequence of the increase of pleural inflammation and decomposition of the inclosed matter, owing to the *long continued* contact of atmospheric air.

Dr. Williams wished to be informed whether the ages of Dr. Roe's patients were stated, and what the mean age of the whole number was; the age of a patient being a very essential element in his chance of recovery from such an operation as paracentesis thoracis. Dr. Roe said that very few of the patients were under 20, several of them over 30. Dr. Williams's impression was against the operation of paracentesis thoracis; he had seen it done repeatedly some years ago, but with such uniformly unsuccessful results that it fell into disuse; nor had later experience offered much to remove his objections to it; but in these cases no adequate measures had been taken to exclude the air from the cavity of the chest. He adverted to the recoveries that frequently took place in cases of effusion into the cavity of the thorax, where no operation was performed: to one in particular, of a lady, where there was great effusion, and such oppression of breathing that suffocation was imminent. Nevertheless this patient recovered satisfactorily, and under the use of very little medicine. Neither did he think that performing the operation at an early period gave any security for its more successful issue—he had seen it fatal whether performed at an early or a late period after the attack. There was great and immediate relief experienced from the operation, but it was not permanent. He thought that the entrance of air after or in the course of the operation into the sac of the pleura, had a most detrimental influence; that the air was apt to occasion a greater amount of pressure than the fluid which it replaced; and secondarily, that by its contact with the matter of the effusion, it produced changes in this which soon rendered it offensive, and the cause of irritative fever, under which the patient almost certainly sunk. He drew a distinction between the effects upon the intercostal spaces of the effused fluid: if it was purulent, there was bulging of these spaces; if it were simply serous, there was no bulging. The diagnosis was further assisted by the general symptoms: with empyema there was hectic, rapid pulse, more of the cachectic countenance than with simple serous effusion. Whilst, with the purulent effusion, he would not oppose paracentesis thoracis, he should not readily yield to the proposal for its performance when he believed that the effusion was simply serous; the natural recoveries that took place from effusion of the latter kind warranted this distinction. He spoke of various means and contrivances which had been adopted and imagined, to prevent the ingress of air by the canula. The operation had been performed at Berlin

the patient being placed in a warm bath at the time; Skoda, of Vienna, had contrived a valvular canula, which, whilst it permitted the freest issue to the fluid, opposed any attempt of the air to enter the chest; others had merely armed the outer end of the canula with a piece of the small intestine of a fowl, which being placed in a vessel of water, acted as a valve, preventing the entrance of air. He thought that a tonic and restorative plan of treatment was, on the whole, more successful than a treatment with mercury, or diuretics, or purgatives, or indeed antiphlogistic medicines of any kind.

Dr. Mayo remarked upon the combination of calomel and quinine, which had been exhibited in Dr. Thompson's case, with the effect of disordering the patient's bowels and making him worse than he was. He did not approve of such incongruous or *antagonistic* combinations of remedies. Medicines which mutually aided each other in their actions were with propriety conjoined; but he did not understand the principle upon which calomel and the sulphate of quinia could be exhibited mixed together.

Dr. Cussham inquired as to the accuracy of the diagnostic symptom between serous and purulent effusion, laid down by Dr. Stokes, and quoted by Dr. Roe, viz. that there was bulging of the intercostal spaces in empyema, and not in serous effusion.

Dr. Thompson had observed that the bulging of the intercostal spaces existed indifferently, or did not appear at all, in cases of effusion of serum as well as of pus. Whilst he believed that the operation for paracentesis might frequently be had recourse to with decided propriety and advantage, he would by no means lay it down as the general rule, that whenever there was fluid effused into the pleura, the chest was to be tapped, and the fluid evacuated. He had seen several cases in which rapid recovery took place in spite of very large effusion into the cavity of the thorax; sometimes, too, the recovery happened under a purely palliative and expectant treatment, and after more vigorous practice had totally failed. He held the admission of air as likely to prove highly prejudicial, and should regard the operation done without any precautions taken to guard such an occurrence as an abuse rather than a right use of paracentesis. He defended the simultaneous employment of mercurials and mild tonics.

Mr. Phillips had been called upon to perform the operation of paracentesis thoracis some fifteen or sixteen times; but he must say he had seen no benefit from the practice: after five or six months not one of the patients who had been operated upon was in life. There was the immediate and great relief that had been signalized by other

speakers on the question; but it was only temporary. He did not think the entrance of air into the cavity of the chest, through the canula, of any consequence; it was soon removed by absorption: the chest, immediately after the operation, might sound like a drum; in a few hours, the air, and along with it the tympanic sound, were gone.

Mr. Hewitt had seen the operation of paracentesis repeatedly performed, but never yet with success. He adverted to the effusions of lymph with which the majority of the cases of serous effusion into the pleura, that would be held subjects for the operation, were complicated: the presence of this lymph he held a serious bar to the success of the operation: in one case he had found both surfaces of the pleura covered with a layer of lymph several lines in thickness, and so tough that he could not burst it by blowing into the lung with a pair of bellows; he had to make several incisions through it before he could inflate the lung. He mentioned a particular case, where effusion, in consequence of pleuritic inflammation, had taken place, and in which the effused fluid (pus) had made its way out by perforating one of the bronchi. The patient gradually recovered, and went on leading an irregular life for several years, always troubled with cough, and always expectorating freely. He finally died suddenly from hæmoptysis. A large cavity was found on one side full of pus, communicating with one of the bronchi of the corresponding side. The fatal hæmoptysis had been induced by the extension of ulceration from the fistulous passage to one of the larger pulmonary vessels, which was thus opened.

Mr. Lloyd had little to say in favour of paracentesis thoracis for empyema: where he had seen it performed the patients had died: he only recollected a single case of recovery under effusion into the pleura where the cavity of the chest was perforated, and here nature was herself the surgeon—she established the opening for herself. He adverted to certain cases in which there is every appearance of effusion into the pleura, in which the matter is nevertheless external to its cavity. One of these cases was of diseased spine—matter had been formed in large quantity, and had diffused itself extensively under the parietes of the chest, so as to simulate empyema.

Dr. Alexander Stewart, of Glasgow, spoke in favour of the operation, and he particularly defended the practice of giving antagonistic medicines under certain circumstances which he specified.

Mr. Arnott on the whole thought favourably of the operation of paracentesis; he had done it on the behest of his colleagues, the physicians of the Middlesex Hospital, several times, and if sometimes unsuccessful—

fully, sometimes also successfully, and in circumstances where, without it, the patient must necessarily have died. He thought it better not to be too anxious to draw off the whole or even a large portion of the effused fluid at once—he had, however, yielded to the anxiety displayed by others to have the chest effectually cleared of fluid—upon one occasion he had removed nine pints of serous fluid—which of course cannot be effected without the entrance of air into the pleura; from this, however, he had never seen any ill effects; the air is in fact very rapidly removed. We should be no more solicitous about the effects of air finding its way into the cavity of the chest after the operation of paracentesis, than we are about that which escapes into the same cavity and surrounding cellular tissue in cases of fractured ribs. With regard to the administration of what Dr. Mayo had characterized as antagonistic medicines, he did not much heed what might be said on theoretical grounds; in practice the plan answered well. In Middlesex Hospital he treated successfully many bad cases of pox in shattered systems by the very compound that had been called in question—mercury and quinine, which he felt persuaded he could not well have dealt with, had he had only one of these medicines at his command.

Dr. Webster advocated the operation of paracentesis, but not from experience, for he had only seen it done in one case, and that died. He illustrated the practice of giving antagonistic medicines, by the daily usage of ordering an acid and an alkali, which, as all the world knew, mutually neutralized one another.

Dr. Mayo explained.

Dr. Kingston thought that the success of the operation of paracentesis was mainly influenced by the period at which it was done: performed in a patient worn out with protracted suffering, it could not be expected to succeed; undertaken at an earlier period, and before the strength of the patient was broken, he thought there was every thing, both on pathological grounds, and grounds of experience, to recommend it.

The President adverted to the rules laid down in regard to the place at which the operation of paracentesis ought to be performed, and quoted two cases from Laennec, in which very disastrous consequences followed from venturing to puncture between the fifth and sixth ribs, reckoning from below upwards—the diaphragm having been wounded in one, the kidney in the other. For his own part, he had performed paracentesis in two instances so low down as between the ninth and tenth ribs, guided to the spot by the assurance of his colleagues, the physicians of St. Bartholomew's Hospital, that there the indications of

the presence of fluid were most unequivocal, and in both instances he neither encountered difficulty, nor did the patient sustain any injury. He had performed paracentesis in five instances; in three the result was favourable, in two it was unfavourable.

Dr. Roe summed up, defending the positions he had taken in his paper, and upholding the operation of paracentesis against the arguments and facts of those who thought less favourably of it than he did himself. He thought he was borne out by the general tenor of the discussion in attributing the frequent fatality to the admission of air within the cavity of the pleura, and to the late period of the disease at which the operation was had recourse to. He totally dissented from the opinion expressed by Dr. Williams that the air exerted more pressure on the already compressed lung than the fluid removed. In all instances, save one, the signs of the presence of air within the chest had quickly disappeared, and in that the unpleasant symptoms were easily removed on the (?) day, by the employment of a common exhausting syringe. His patients were mostly between 20 and 30 years of age, and in one instance, in answer to Mr. Arnott, he stated that as large a quantity as eight pints of serous fluid had been removed. He had not advised the operation in all cases of pleuritic effusion, but only in certain cases where medicinal agents seemed inadequate to effect its removal; and then he thought it should be employed early, and before the lung become so bound down as to be incapable of again expanding and resuming its function.

The next meeting will be held on Tuesday, May 14th, 1844.

MICROSCOPICAL SOCIETY.

April 17th, 1844.

J. S. BOWERBANK, Esq. F.R.S. IN THE CHAIR.

A PAPER was read by John Quekett, Esq. F.R.S. on some phenomena connected with the movement of the cilia in the common mussel (*mytilus edulis*). After some observations on the nature of ciliary movement in general, and on the various opinions of former observers respecting it, the author stated that, in the common mussel, the cilia occur on the branchiæ or gills, which are four in number, two layers being situated on each side, between the lobes of the mantle. Each layer consists of rays of vessels running parallel to each other, like the teeth of a comb; and the cilia are situated on the margins of the rays, there being two rows to each ray. The observations in the paper relate more particularly to the motion of the cilia on the sides of the inner layer of the gill ray. If one of these rays be placed, with

the inner side upwards, on the object plate of the microscope, each row of cilia will be found to present, besides the usual curved, whip-like motion in a vertical plane, another slight but yet important movement on itself in a direction nearly at right angles to the preceding, extending through the space of a quarter of a circle, the motion being analogous to that which is effected by the quill feathers in the wings of birds, or, to use a more common example, by the "feathering" of the oar in rowing. In order to observe this movement in the most satisfactory manner, the motion of the cilia should have nearly stopped, and that part of the cilia attached to the gill, which may be termed the root, being examined with a power of at least 400 linear, this peculiar motion will be easily perceived. Mr. Quekett considers that the propulsion in one direction of the fluid acted on by the movement of the cilia, is chiefly effected by this peculiar arrangement; indeed, without some arrangement of the kind, motion of a fluid in one determinate direction could not have been effected.

ON THE CRYPTOGAMIC VEGETABLE

WHICH CONSTITUTES THE CONTAGIOUS
DISEASE DESCRIBED UNDER THE NAMES

Teigne Tondante, or *Herpes Tonsurans*,
(*Porrigo Scutulata*, WILLAN; *Trichosis*
Scutulata, WILLIS.) BY M. GRUBY*.

THE affection spoken of here is that with which we are so familiar in England, characterised by the partial loss of the hair in patches, and the formation, in the places denuded, of rounded areas covered with small whitish scales, and little asperities, similar to those presented by the healthy integument exposed to cold, and called *goose-skin*. An attentive examination of fragments of the hair from a patch affected in this way, shows the tissues of the hair filled with cryptogamia, and still covered with the epidermic scales when the interior is full of sporules. The sporules are round, oval, transparent, colourless, smooth on the surface, and full of a homogeneous matter; the cryptogamic plants themselves arise in the interior of the roots of the hairs, under the form of a mass of round sporules, from whence a crown of articulated filaments is gradually developed, which, in their growth, creep along in the interior of the hairs in lines parallel to their axes. As the hair grows, the cryptogamia which it includes in its interior grow also, until the shaft has passed beyond its follicle. The quantity of sporules is so great that they fill the substance of the hair completely, and fairly make its proper structure invisible.

The development of cryptogamia appears

to begin in the roots of the hairs; these are the parts first affected, at all events, and they may often be found opaque, full of sporules, and altered in appearance, the rest of the hair being quite healthy. As the parasitic plants grow, the hair becomes more and more opaque, and when they have completely pervaded its structure, it is grey, opaque, possessed of little elasticity, and so brittle that the slightest touch suffices to break it; it is farther increased in diameter; but although thus seriously implicated it still continues to shoot. The hairs generally break off short at the distance of a few lines from the surface of the scalp; sometimes they break before they have escaped from their sheaths, and then the little canal which would have given them passage becomes plugged up with sebaceous matter, which hardens by exposure to the air; and this mass, carried forwards upon the point of the hair, forms a somewhat opalescent elevation, which has often been mistaken for a vesicle; it is a mass of dried sebaceous matter, mixed with epithelial scales in large numbers, and traversed by one, two, or three weak coiled-up hairs full of sporules, or supported upon an hypertrophied stump in the same condition. These are the elevations which give to the affected part the appearance of goose-flesh.

The parasite whose evolution constitutes this porrigo, or trichosis *scutulata*, differs entirely from that which causes the porrigo, or trichosis *decalvans*. That of the former presents itself in the form of chaplets of sporules, and very rarely extends into branches; that of the latter, on the contrary, is numerously branched, waving, and the sporules are placed on its sides; in the porrigo *scutulata* the sporules are turgid, and fill the roots, and shafts of the hairs; in the porrigo *decalvans* they are extremely minute, and are situated on the exterior of the hairs, which they surround as with a true sheath. In porrigo *scutulata* the sporules are formed and developed under the skin in the piliferous follicles; in the porrigo *decalvans*, again, they are only evolved on the part of the hair which has passed the surface.

NOTE ON CERTAIN CRYPTOGAMIC VEGETABLES,

DEVELOPED IN GREAT QUANTITIES IN THE
STOMACH IN A CASE OF DYSPHAGIA AND
CHRONIC VOMITING. BY M. GRUBY*.

PARASITIC plants have now been detected upon the mucous membranes of the living body in many situations, particularly upon the aphthous mouth of infants. In a patient who had suffered eight years from dysphagia, and constant inability to keep food on her

* Comptes Rendus, No. 14, 1 Avril, 1844.

* Comptes Rendus, Avril 1, 1844.

stomach, considerable quantities of white angular fragments were very regularly observed. These, brought under the microscope, were found to consist of agglomerations of round or oval sphorules, transparent, smooth on the surface, homogeneous, smaller sporules being occasionally seen on the surface of larger sphorules, as in the *torula cerevisia*, or yeast plant. The food of the patient was carefully examined for several days in succession, and found to contain no cryptogamia. By means of an œsophagus tube, fitted with a sponge in the interior, which could be made to project and absorb the moisture of any point of the œsophagus or stomach, it was satisfactorily ascertained that the cryptogamia in question were produced in the lower third of the œsophagus and in the stomach. No perfect plant was obtained; only sporules in masses, and fragments of filaments; so that the species could not be ascertained. This much was made out, however; that the parasite here had no resemblance to the trichosporum of aphtha.

WESTMINSTER HOSPITAL.

REPORT OF CASES, WITH REMARKS.

BY BENJAMIN PHILLIPS, ESQ.
Senior Assistant Surgeon to the Hospital.

Fractured Ribs, with Injury to Lung.

SAMUEL POOLE, æt. 32, a wine-cooper, admitted Feb. 28, at a quarter past seven, A.M. having been jammed between a cart and a waggon. On examination, several of the ribs were found fractured, and being in a state of collapse on admission, six ounces of brandy were administered during the night to produce reaction.

At 10 o'clock A.M. of the 29th, the breathing was very hurried, 76; face livid; pulse 138, hard and jerking; expectoration nearly pure blood, but mixed with frothy mucus; sound on percussion tympanitic, particularly under the scapula of the left side, and air could be felt under the skin by the finger, imparting a crackling sensation. Was bled to $\frac{3}{4}$ xvj. and a dose of castor-oil given. At 1 P.M. was seen by Mr. Phillips, and was then no better. Ordered to be again bled, and to take the following powder directly—

R. Ant. Pot. Tart. gr. $\frac{1}{2}$; Mag. Sulph. $\frac{3}{4}$;
Aque puræ, $\frac{3}{4}$. every six hours.

At 5 P.M. breathing better, 54; pulse 128, much softer.

March 1st, 10 A.M.—Considerably better; breathing 42; pulse 124, soft and compressible; expectoration less bloody; had not slept much during the night; cough troublesome; at 2 P.M. breathing 40; pulse 110.

2nd.—Respiration 36; pulse 96, soft; cough less troublesome; slept well; expectoration free from blood. Cont. Med.

3rd.—Respiration 46; pulse 98; cough troublesome; slept well.

4th.—Slept well; respiration 38; pulse 96, compressible; has coughed a good deal; expectoration slightly tinged with blood.

R. Hyd. Chlorid. Pulv. Antim. aa. grs. ij.
ft. Pulv. nocte manequæ sumend.

5th.—Doing well; pulse 84; respiration 36; cough troublesome.

6th.—Pulse 78; copious expectoration, streaked with blood.

7th.—Pulse 76; better; respiration 30.

8th.—Pulse 84; gums rather sore; complains of pain upon coughing in the left side and beneath the scapula.

9th.—Pulse 86; cough troublesome; respiration 44; mouth very sore; complains of sickness and pain in the stomach; no appetite. To discontinue the Hyd. Chlorid. and take the following draught every six hours.

R. Pot. Carb. $\frac{3}{4}$;
Acid. Hydrocyan. $\frac{m}{ij}$;
Mist. Camph. $\frac{3}{4}$. M. ft. Haustus.

10th.—Sickness relieved, but cough is very troublesome; pulse 88, small.

11th.—Still pain on inspiration; had not slept during the night on account of the cough being very troublesome; pulse 86.

App. Emp. Lyttæ lateri. Cont. med.

12th.—Much relieved by the blister; cough better; pulse 80, soft.

13th.—Better.

14th.—Pulse 96; cough troublesome at night. To have a cough mixture: a dose to be taken frequently.

16th.—Cough troublesome, with pain in left side; pulse 104.

Rept. Empt. Lyttæ.

17, 18, 19.—Much the same.

21st.—Considerable dullness on percussion on the left side as high as the third rib, and he is unable to lie on that side; cough troublesome.

Rept. Emp. Lyttæ.

24th.—Improving; less dullness; cough better.

28th.—Continues much the same; cough keeps him awake at night.

31st.—Sound on percussion clearer; cough better. To have full diet.

April 6th.—Much the same as at last report.

Rept. Emp. Lyttæ, and to take Hyd. Chlor. grs. ij. nocte manequæ.

10th.—Mouth rather sore, but greatly relieved; can now lie on either side; cough better. Cont. Med.

12th.—Improving fast, but mouth sore. To take one powder at night only.

14th.—Better.

16th.—He left the hospital, greatly relieved.

REMARKS.—The preceding case was one of fractured ribs, with severe injury done to the lung by the fractured bones. The lung was perforated; the air escaped into the pleural cavity, as was shown by the drum-like sound on percussion; a certain portion of air made its way into the cellular tissue, and occasioned on the application of pressure a crackling sound. When seen at 1 o'clock on the 29th of February, the symptoms were so severe that but small hope of his recovery could be entertained. The pulse was rapid, but weak; the respiration was extremely hurried and embarrassed. A vein was largely opened, and the effect of the loss of blood carefully watched. The oppressed pulse was gradually relieved, it became less and less laboured, but the blood continued to flow until syncope was very imminent. He was then brought under the influence of tartar emetic, and the symptoms of pneumonia rapidly subsided. When the acute symptoms were completely relieved, there remained evidence of consolidation of the pulmonary tissue, and of fluid (blood or other) in the chest. The patient was then subjected to mercurial action, with decided benefit, but it was still evident that fluid remained, and blistering was resorted to with much relief. After a time, the pulse still keeping up, further mercurial action was induced, and the amendment was very striking.

Œdema Glottidis; tracheotomy; death.

A. B., aged 20, was admitted into Percy Ward, with acute synovitis, for which a number of leeches were applied. Erysipelatous inflammation followed the application, which under common fomentations and saline medicine gradually abated. Her pulse, however, maintained its frequency, with some feverish excitement. She remained in that state some days, when she began to complain of some soreness of the throat, which rapidly increased, and the next morning it was accompanied by difficulty of breathing, which became every hour more threatening.

At 1 o'clock a consultation was held upon the case: 24 leeches were applied to the throat, but they produced no relief: the dyspnoea increased, and tracheotomy was determined on. Mr. Phillips performed the operation at once: every step of the operation went smoothly, and instead of the violent efforts which were previously necessary, the respiration became perfectly quiet, but she gradually sunk, and died in the evening.

Upon a post-mortem inspection next morning, the organs found diseased were the lungs, the pharynx, and the larynx. There was diphtheritis, or pultaceous inflammation of the pharynx; it extended to the

glottis, and produced œdema glottidis of so decided a character, as to completely block up the opening. The lungs were thoroughly gorged with blood, but there was no structural change in any part of their substance.

REMARKS.—It may be asked in this case, as the relief to the breathing after the operation was so marked, why did the patient die? It might be maintained, with some show of likelihood, that her life was so far prolonged, merely by the stimulus kept up in the exaggerated efforts to breathe, a kind of death struggle, and that when the effort was no longer necessary, the stimulus was no longer conveyed, and the blood accumulated in the lungs until the patient died asphyxiated; or otherwise, and probably with more of physiological truth in the supposition, it might be said that the struggle so long continued for breath, and the amount of muscular effort required to fetch it, combined with the imperfect decarbonization of the blood, produced such a degree of exhaustion, and impaired so seriously the processes upon the aggregate of which life depends, that the free supply of air came too late; the system could not recover itself, and death happened just as if nothing had been done. There is, perhaps, no operation which the surgeon is called on to perform, which he does with more reluctance than that of tracheotomy, in cases like the present; for it almost always happens that his services are not required until irremediable mischief is done to the lungs. In the present case, the operation was too long delayed; there seems little doubt that had it been done three hours earlier, the patient's life might have been saved.

Hæmorrhoidal excrescences; prolapsus ani; ligature of tumors; cure.

George Wear, æt. 37, gardener, admitted into Mathew Ward, Dec. 27, 1843, with hæmorrhoids and protrusion of the rectum. States that he has had piles upwards of fifteen years, and that during the first few years they bled occasionally. In 1834, he consulted a medical man, who scarified the gut, and applied some species of escharotic. He attended this surgeon for 18 months, and derived considerable relief, then had no medical assistance, for several years, when they again became very troublesome, and he was advised to apply leeches and fomentations, which afforded temporary relief only. He continued thus until they became so painful as not to permit him to follow his employment, and the protruded mass could not be kept up at all. He then came to the hospital.

Dec. 30.—Mr. White scarified the rectum, and ordered him to take the following draught—

℞ Tr. Opii ℥xxv. Mist. Cretæ, ʒijs.

Jan. 6.—He was again scarified, and the draught repeated. The scarifications were continued once a week up to

Feb. 12, when Mr. Phillips ordered him a dose of

Hyd. Chlorid. followed in two hours by Ol. Ricini, ʒss.

13th.—Mr. Phillips applied a ligature on one of the projecting masses, and ordered him to take

Conf. Sennæ, ʒj. omni nocte.

March 2.—Great deal better, a small portion only protruding, to which a ligature was applied.

Cont. Conf. Sennæ.

12th.—States that whilst at stool a small portion descends, but not at any other time.

16th.—Discharged cured.

REMARKS.—This patient had large hæmorrhoidal excrescences, accompanied by considerable protrusion of the rectum, which could not be reduced without much difficulty. Protruded rectum in adults is very commonly accompanied by hæmorrhoids, and is mainly caused by them. Mr. Hey, of Leeds, proposed a plan of cure in such cases,—the ligature or excision of the hæmorrhoidal tumors. In the present case, the tumors were large, and the prolapsed intestine much thickened. The plan first adopted was to unload the hæmorrhoidal vessels, by means of extensive scarifications. It was repeated again and again, but not with much success. Under these circumstances, Mr. Phillips tied a portion of the diseased mucous membrane; but so aggravated was the case that new points had to be tied several times before the evil was subdued. He remarked that this condition of the rectum rarely exists without constipation, and that in all cases the first step should be to get the bowels into a good state by the use of mild aperients, such as Conf. Sennæ, Sulphur, and Jalap. It not uncommonly occurs that this plan renders any operation unnecessary, and that in no case should this comparatively trifling operation be had recourse to when the general health is in an unsatisfactory state, lest phlebitis should follow.

THE NEAPOLITAN PHLEBOTOMIST.

THE taste for blood-letting is universal at Naples. On every the slightest indisposition, or fear of indisposition, all men, women, and children, run to the *Salassatore*, or phlebotomist, to have a little blood drawn from the back of their hand; so that there is not a lad or a young girl of 10 or 12 years of age whose hands do not bear testimony to the repeated applications of the *Salassatore's* lancet. For a faith which has not a single

heretic in the community, of course there is a priesthood—a numerous priesthood. The number of educated medical men would never suffice to perform its offices. This has led to the establishment of a special corporation, whose business it is to handle the lancet, and attach the leech. The phlebotomists have therefore establishments in every street, in every open place at Naples. How often have I paused before the singular insignia by which the shops of these priests of the lancet are distinguished! Imagine to yourself the figure of a man, naked as when he dwelt in paradise, but spirting forth from every vein which steel can reach parabolic jets of blood, an ample pool of which is at the same time collected on the ground. Imagine further, by the side of this awful figure, the effigies of the artist appropriately habited, lancet in hand, and on his knee before his work, like Pygmalion before his statue, and you will have a notion of the way in which the *Salassatore* here brings the fine arts to his assistance! I was curious to penetrate into one of these sanctuaries of minor surgery, and see its priest close at hand, and seeking some pretext for my intrusion, I demanded a few leeches. I found the phlebotomist at the further extremity of his shop, gravely extended upon a settee of straw, and waiting for a customer with that Neapolitan indifference which resembles at once indolence and sleep, or is in fact a mixture of the two. The shop was poorly furnished, but the walls were occupied from the floor to the roof with a frame-work of little compartments or pigeon holes, filled with compresses and bandages rolled neatly up. I ventured a question on the subject, and learned with amazement that each compartment represented a *customer*, whose fillet and compress were there in readiness. I stepped back a pace, before the sanguinary statistics which the answer of the Neapolitan *Salassatore* presented to my mind's eye, and did justice at length to the *moderation* of our Parisian phlebotomists who draw blood on the *coup sur coup** system!—*M. Carrière, in Gaz. Méd. de Paris*, No. 13, 1844.

PROXIMATE CAUSE OF DIABETES.

At the meeting of the Academy of Sciences of Paris of the 15th inst., a memoir by M. Mialhe, entitled, "A Theoretical View of the cause of the Disease known under the name of Diabetes Mellitus," was presented. The author in the course of his examination of the urine in a case of doubtful diabetes, was led to discover, as he says, that grape or diabetic sugar only acquires a reducing action upon the oxide of copper after having been chemically acted upon, or altered by an

* Query, *cup upon cup*, till the patient expires?—*Eng. Printer's devil*.

alkaline substance, free, or in the state of carbonate. This simple fact he conceives has given him a key to the primary cause of the disease, characterized by the presence of sugar in the urine. M. Mialhe maintains that the hydrocarbons used as food, such as sugar, gum, starch, &c. are incapable of being assimilated until they have been transformed by the alkalis of the blood into new substances, among the number of which figures one endowed with very energetic deoxydating properties, so that it readily reduces the peroxide of lead to the protoxide, the salts of the peroxide of iron into salts of the protoxide, salts of the binioxide of copper into salts of the protoxide, and even to the metallic state. Now in the patient who is affected with diabetes, the normal changes cannot go on, because, as he does not perspire, and all the cutaneous exhalations are acid, no free alkali or alkaline carbonate can exist in the blood, by which the primary cause of the assimilation of sugar becomes impossible. The simultaneous use of diaphoretics and alkaline medicines is the course which M. Mialhe recommends as most likely to enable us to master the disease.

CONSTITUTION

AS TO

AGE AND MORTALITY

OF THE ROYAL ACADEMY OF MEDICINE OF PARIS, AND COUNCIL OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

THE Royal Academy of Medicine, of Paris, has among its ranks 8 members of 80 years of age and upwards, 20 of 70 and upwards, 40 of 60 and upwards, 44 between 50 and 60, 24 between 40 and 50, and 3 between 30 and 40. The mortality in the course of the last four years was 25, which is exactly at the rate of $6\frac{1}{4}$ per cent. or about 1 in 23.

We should have much difficulty in getting at an *aperçu* of this kind in regard to any of our own scientific or professional institutions; but at the Royal College of Surgeons, members of the Council appear to have been commonly chosen when they were from 45 to 47 years of age, and the mortality is stated at rather more than 1 from the body annually: in the course of the last 16 years there have been 17 deaths. There is a rough way of estimating the probable duration of a life by subtracting the age from the number 86, and halving the difference, which is the sum required. Suppose a member of Council to be 46 on his election, his chance of life upon this basis comes out 20 years; and this number, as there are 21 councillors, we see is as nearly as possible the truth.—We have satisfaction in giving those among our brethren who may “achieve the honour” of becoming a member of the Council of the Royal College of Surgeons, upon the new

arrangements, the elements of a simple calculation by which they may see how long they are likely to enjoy their distinction. We would not hang a Damocles' sword over heads, but merely, as in the case of the triumphant victor of old, be at their ear to whisper into it:—Remember, thou art a man!

TRANSFORMATION OF FIBRINE INTO BUTYRIC ACID.

At the Academy of Sciences of April 15th, M. Dumas presented a memoir of M. Würz on the above subject. Fibrine left to itself for a week exposed to the air, is decomposed into albumen, carbonic acid, acetic acid, and ammonia. M. Würz adds, that albumen, caseine, and albuminoid matters in general, will probably be found to suffer the same changes as fibrine under the same circumstances. The fatty volatile acids being intimately connected with the neutral fatty substances, it may be imagined that, under certain circumstances, fibrine should become changed into a fatty neutral body, and that such a change may even be brought about artificially. M. Würz has also succeeded in disengaging albumen from all foreign or adventitious matters, without destroying its solubility in water.

At the same meeting of the Academy, M. Blondeau de Carolles gave an account of an experiment in which he had seen cane sugar transformed into acetic acid under the influence of caseum, without either losing or absorbing anything.

IS SYPHILIS OF AMERICAN ORIGIN?

MR. PRESCOTT, the distinguished author of the “History of Ferdinand and Isabella,” took occasion in that work to express his conviction that the venereal disease did not exist among the native Americans at the time of Columbus's discovery.—There is no allusion to it in the narratives of Columbus himself, nor of his son Ferdinand, nor indeed in any other record of the Spanish adventurers. In a recent letter to Dr. Hosack, of New York, he says:—“I have been led into a much wider range of observation in preparing the ‘History of the Conquest of Mexico.’ But it has served to confirm my former opinion, since I have never met with a notice of this disease, or of any which resembles it. The ancient chronicles speak of an Indian epidemic, called the *Matlazahuatl*, which swept off great numbers of the natives both before and after the Conquest, and which seems to have had some resemblance to the yellow fever. They also notice the introduction of the small-pox by a black, who came into the country the year after the

arrival of Cortes. The Spaniards would certainly not have omitted to notice so terrible a disorder as the venereal, had it been found among the natives; especially as, considering their own licentious indulgence, it must have fallen very heavily on themselves. Their uniform silence, therefore, is evidence so strong, that it may be called positive rather than negative, and may be considered as establishing the fact, that the disease was not known in the Mexican empire at the time of its discovery. Whether a disease so easily propagated among adjacent tribes, and which seems to be circumscribed by no parallel of latitude, could have existed in other parts of the Continent without finding its way into Mexico, is a question which your own knowledge of the subject will enable you to determine better than I can."—*New York Journal of Medicine*, March 1844.

The disease entitled *Matlazahuatl* is considered by Humboldt as having a great analogy with yellow fever, or black vomit.

JENNER AND NAPOLEON.

DURING the savage war that raged between France and England, when Napoleon had all Europe, with the single exception of Great Britain, at his feet, and many of our countrymen were languishing in French prisons, the only avenue to the conqueror's heart, for some little indulgence to these unfortunates, was through Edward Jenner and the Empress Josephine.—Jenner wrote the petition, the kind-hearted Josephine presented it,—and upon several occasions with success. At length Napoleon interdicted any new applications of the sort:—"Thou knowest, my sweet friend," he said, "I can refuse thee nothing which thou askest IN THE NAME OF THAT MAN;—my sense of duty to the state informs me that I do wrong in yielding to thee; so let me be tempted no more." Wherefore has not civilized man from the four corners of the globe combined to rear a monument in every land, in every town, to the name and memory of Edward Jenner? Our DESTROYERS have columns and statues in our public places: shall our PRESERVERS lack memorials of our grateful remembrance? The French have lately raised a monument to Molière; the Brusselers have dedicated a statue to Vesalius;—why should not we follow with one to Jenner?

MR. STANLEY ON THE DISEASES OF THE BONES.

WE are happy to observe, in Messrs. Longman and Co.'s last monthly list of publications that have just appeared, or that are about to appear, an announcement under the latter head of the work of the Surgeon of St. Bartholomew's Hospital which has been so

long looked for by the profession. Mr. Stanley gained the Jacksonian Prize from the Royal College of Surgeons, it is now 20 years ago, the subject of the essay being Diseases of Bone; and it is well known that, ever since this time, he has been sedulously engaged in collecting original materials for a great work upon the entire pathology of the osseous system.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

List of Gentlemen admitted Members, April 26.—J. P. M'Donald.—J. T. Mosgrove.—W. H. Benson.—H. E. F. Shaw.—B. S. Browne.—R. W. Coe.—R. King.—H. F. Dakers.

APOTHECARIES' HALL.

Gentlemen who have received Certificates, April 25.—A. C. Barker, Hereford.—H. E. Brewer.—C. Townsend, Sydnall, Shropshire.—R. Clark, Lancaster.—G. S. Deane, Liverpool.—K. Tomson, Luton.—T. Clarke, Banbury, Oxon.—H. Fearnside, Otley, Yorkshire.—A. J. Tapson.—C. J. Rix, Manchester.—N. Brangwin, Henley on Thames.—M. J. Tayler, Bath.

MORTALITY IN THE METROPOLIS.

Deaths from all causes registered in the week ending Saturday, April 20.

Dropsy, Cancer, Diseases of Uncertain Seat	98
Diseases of the Brain, Nerves, and Senses	141
Diseases of Lungs and Organs of Respiration	262
Diseases of the Heart and Blood-vessels	25
Diseases of Stomach, Organs of Digestion, &c.	45
Diseases of the Kidneys, &c.	9
Childbed	7
Paramenia	0
Ovarian Dropsy	0
Disease of Uterus, &c.	2
Arthritis	0
Rheumatism	0

ON THE CHEMICAL PHENOMENA OF RESPIRATION.

BY M. GAY-LUSSAC;

With Preliminary and Concluding Remarks.

—
If there be one function more immediately indispensable to life than another, it is respiration. The brain and spinal marrow may be destroyed, and all sensuous life abolished, but if respiration be kept up, heat will be engendered, the heart will go on beating, the muscles will retain their irritability, digestion and secretion will apparently proceed—in short, somatic life will be maintained for a certain, often a very long time. Strange to say, however, the very essence of the all important function that goes forward in the lungs is still matter of discussion among physiologists, and it is therefore with sincere pleasure that we observe the oldest and most distinguished chemist of France engaging, and promising to engage further, in the question. In the "Comptes Rendus des Séances de l'Académie des Sciences" of April 1st, will be found a kind of prodromus to the future labours of M. Gay-Lussac.

Our readers are aware that the physiological world is divided between two opinions on the subject of the chemistry of respiration. According to one, and this was first propounded by Black, and advocated without mention of his name by Lavoisier, the formation of carbonic acid and of water takes place in the lungs themselves, and in virtue of the mediate contact of the oxygen of the inspired air with the blood contained in the delicate blood-vessels of these organs. According to the other view, the oxygen of the air does not act immediately upon the blood in the capillaries of the lungs; it is merely absorbed there; the chemical phenomena in which it is influential or aidant take place without the lungs in the course of the general

circulation; and it is only on the return of the blood to perform its lesser circuit that it gives off the products of the oxydizing processes that have already taken place in its mass.

The latter theory, imagined by several physiologists before him, is, however, peculiarly indebted to M. Magnus for its development, and for the grounds upon which it was accepted in the world of science. The grand object of Magnus was of course to prove—1st, the presence of carbonic acid in the blood; 2d, the different proportions of carbonic acid, and of atmospherical air or oxygen, in the blood of the two orders of its containing channels—the arteries and veins. The assent of more than one distinguished chemist, and the silence of criticism, appears to have stamped the inquiries of M. Magnus with a kind of authority, which, however, M. Gay-Lussac cannot allow to his conclusions, these presenting themselves to his mind by the side of many and grave doubts, and Magnus's inferences being sometimes even in opposition to those which his facts would warrant.

The means resorted to by Magnus to disengage the carbonic acid from the blood, and so to prove its existence there, are familiarly known: he replaced it by hydrogen or another gas, and ascertained its quantity by means of caustic potash. From the blood he readily obtained a large quantity of carbonic acid; but did he procure more from venous than from arterial blood? This is the vital question in the theory he espouses; his own statements, however, show that he did not; on the contrary, he appears to have obtained less: as a mean of five experiments, for example, from 100 of arterial blood he procured 6.496 carbonic acid, and from 100 venous blood but 5.504 of the same gas; arterial blood consequently appears to contain considerably more carbonic acid than venous blood! a result which, if accurate, evidently destroys the entire theory.

This grand contradiction, however, is

not the only one. Either kind of blood contains oxygen and azote as well as carbonic acid. If azote be formed in the course of the circulation, as all accurate physiological experiments unite in proving that it is, the quantity of this gas ought to be less in arterial than in venous blood. But what say the figures in Magnus's experiments? That arterial blood contains half as much azote again as venous blood: whilst the mean quantity of azote in 100 of arterial blood is 1.513, in 100 venous blood it is no more than 1.008.

The relative proportions of oxygen alone seem at first sight to agree with Magnus' theory. 100 of arterial blood yields 2.417, 100 of venous blood but 1.170, or about one-half less of oxygen. But when we look more narrowly at this statement, says M. Gay-Lussac, and examine its consequences, it is obvious in the first place that as the carbonic acid which makes its appearance during the act of respiration is formed at the expense of the oxygen absorbed by the blood, there must be a certain relation between the volumes of these two elastic fluids. If, for instance, we know the relative volume of carbonic acid expired in a given interval, we also know that the corresponding volume of oxygen absorbed must be at least equal to it; and this condition established, it would not be difficult to learn whether or not it was borne out by the results of direct experiment. Unfortunately the conclusions of M. Magnus, in regard to the quantities of carbonic acid and of oxygen discovered in arterial and in venous blood respectively, are mutually subversive, and must needs be held as utterly insufficient to afford grounds for any safe conclusion.

In default of the positive data, then, which ought to have resulted from the labours of M. Magnus, we cannot do better than take those which we require for conclusions of any kind from the same sources as himself: let us take them from Davy.

1st. Davy informs us that a man expires thirteen cubical inches of carbonic acid gas in a minute.

2d. That the heart, at each pulse, expels one ounce of blood; and taking the number of contractions at 75 per minute, 75 ounces, or 115.7 cubic inches of blood, will pass through it in the same interval of time. Now 115.7 cubic inches of blood having given off 13 cubic inches of carbonic acid, 100 of blood will contain 11.23 of this gas, a quantity which the blood might readily part with, inasmuch as M. Magnus admits, from his experiments, that it contains much more than 20 per cent. of the gas. But supposing that the venous blood gave off 11.23 per cent of its volume of carbonic acid, it is evident that, to produce this, arterial blood ought to contain—must con-

tain—at least an equal volume of oxygen, say 11.23. Moreover, as in the respiratory act, of 4 parts of oxygen absorbed 3 go to form carbonic acid and 1 to form water, the blood must have taken up or dissolved, in its course through the lungs, not only 11.23 oxygen, but $11.23 + \frac{11.23}{3} = 14.97$, a quantity which is 16 times greater than the 0.926 of oxygen which pure water can dissolve in the same circumstances, that is to say, in contact with atmospherical air*. And, farther, if we allow, with M. Magnus, that venous blood, on reaching the lungs, still contains about one-half of the oxygen originally dissolved in the arterial blood, the whole quantity which the latter ought to contain at its exit from the heart will be, first, 14.97 destined to be used up in forming carbonic acid and water, plus 7.48, remaining in the venous blood; in all 22.45, a quantity which would require us to suppose that, in contact with an atmosphere of oxygen, 100 of arterial blood could take up $22.45 \times \frac{100}{0.926} = 106.9$, or more than its own volume of the gas. Such a capacity in arterial blood to dissolve oxygen, eighty times greater than that possessed by water, is certainly not impossible; but it were very necessary to prove it, or at least to give some facts which should render it probable. I am ready to admit, says M. Gay-Lussac, that the data which both M. Magnus and I have assumed are not so unimpeachable as seems desirable, and that ample concessions may be made in regard to them: still, in changing them greatly, the objections derived from such an extraordinary solubility of oxygen in the blood would be entitled to very serious consideration. In this reasoning, simple solution, not chemical combination, is supposed; and this, indeed, M. Magnus adopts; he could not do otherwise; had he admitted combination, he would of course have been asked, wherefore the final effect of respiration was not at once produced? wherefore an action divided into two stages, one in the lungs, the other beyond the lungs in the systemic capillaries? The whole of the gases, then, which have part, or which appear, in the course of respiration, must be held as simply dissolved in the blood, not as chemically combined with it, according to the laws established by Dalton.

The better to enlighten the interesting question of the chemistry of respiration, M. Gay-Lussac then goes on to make fresh applications, with data partly different from those which have been hitherto brought into requisition, viz. the late experiments of M. Bouguery; but still finds that the blood can

* From certain old observations, common to M. Gay-Lussac and M. de Humboldt, it was found that water, in contact with air, contains $\frac{1}{16}$ of its bulk of that elastic fluid, composed of $\frac{1}{3}$ oxygen—0.926, and $\frac{2}{3}$ —1.062 azote.

by no means be supposed to hold such a quantity of carbonic acid in solution as will supply the amount that is given off in a given interval of time; no more can the arterial blood be demonstrated to absorb or dissolve such a quantity of oxygen as will prove adequate to the formation of the carbonic acid and water that are thrown off by the venous blood in the course of its transit through the lungs. The experiments of Magnus, in short, satisfy scarcely any one of the requisite conditions; and his conclusions are seldom in harmony with the data upon which he operates.

M. Magnus explains the change of colour in venous blood entirely by the loss of carbonic acid in the lungs. But it is by no means demonstrated that venous blood exhales carbonic acid in the lungs; and then if it were, the quantity of carbonic acid which it does not give off, according to M. Magnus, is still so great in comparison with what it does eliminate, that it appears impossible to explain by a difference in quantity, relatively so small, any change of colour so remarkable. It is therefore obvious, that the theory of respiration advocated by M. Magnus and espoused by so many physiologists, has as yet no sure foundation to rest upon, and that the chemical phenomena of this vital act require to be examined and discussed anew. M. Guy-Lussac would probably have felt that such a task was too much for him alone, but aided by M. Magendie, he trusts that from their united labours some results may be obtained which shall serve to advance our knowledge of the important function of respiration.

The fine-drawn theories of respiration of late chemists have always appeared to us little less than puerile: oxygen is absorbed or dissolved by the blood in the lungs; it does not combine directly with the hydro-carbons of the blood to form carbonic acid, but these first undergo conversion into lactic acid, which seizing on the soda of the blood converts this into lactate of soda, but the lactic acid becoming incessantly farther oxidized, is in its turn converted into carbonic acid, which being disengaged from the soda by a fresh portion of lactic acid, is dissolved in the mass of blood till it is thrown off in the lungs in virtue of the law of penetration—a certain measure of oxygen is absorbed, and a corresponding measure of carbonic acid is expelled. When we have a lamp burning before us, however, we have not yet imagined the necessity of any roundabout way of securing the combination of the oxygen of the air with the hydro-carbonaceous matter presented to it by the wick. But by the process of digestion, by the solution and elaboration of the alimentary matter, which is effected in the stomach and lacteal vessels, the hydro-

carbons of the blood are prepared for facile combination with the oxygen of the air taken into the lungs; and whatever chemists may have imagined to the contrary, every fact in physiology seems to give us assurance that the union between the oxygen of the air and the carbon and hydrogen of the blood takes place in the lungs. Were it otherwise, were oxygen merely absorbed in the lungs, true respiration performed in the systemic capillaries, the extreme parts of the body would be hotter than the centre; the tide of venous blood that is pouring into the right side of the heart would be warmer than that which is leaving the left side. But this is not so; John Davy ascertained that the temperature of the blood in the left ventricle was from 1° to 3° Fah. higher than that in the right ventricle; and this result has been recently confirmed by Becquerel and Breschet, and indeed by every careful experimenter since he published. The additional temperature, however, could only have been acquired in the lungs, and there only as a consequence of combinations effected between the oxygen of the in-breathed air and the carbonaceous and hydrogenous elements of the blood. This was the simple, and to our minds satisfactory theory of respiration taught by Black, Crawford, and Lavoisier, and that has but just found a new and an able advocate in Dr. S. L. Metcalf, in his work on Caloric, of which we purpose giving some account in our next number, but whose general conclusions upon this interesting subject we add in this place. They are these:—

"1. During the passage of the dark venous blood through the lungs it parts with variable proportions of carbon and hydrogen that unite chemically with atmospheric oxygen, to form carbonic acid and water, as in ordinary combustion, by which it acquires *an addition of caloric* and a bright florid hue.

"2. During the circulation through the systemic capillaries, the caloric obtained from the atmosphere is transferred to the solids, by which their temperature and vitality are maintained, after which the blood returns to the right side of the heart of a dark modena hue, having lost its power of stimulating the organs until it acquires an additional new quantity of caloric from the lungs."

Our readers will at once perceive that here is the announcement of a new principle in physiology, which demands the most serious attention of anatomists, chemists, and natural philosophers. By the alternate addition and subtraction of caloric to and from a little water, we have the power of the steam engine developed; wherefore should not the principle of motion in the animal body be the same? M. Gay-Lussac, with

* Op. cit. 554.

the able assistance of M. Magendie, proposes to go over the ground of the theory of respiration again : who will not rejoice to learn the fact ? We would very respectfully request his attention to the work from which we have made the short extract above.

ON THE
DECREASE OF DISEASE THROUGH
THE PROGRESS OF CIVILIZATION.

By C. F. H. MARX, M.D.

Professor of Pathology in the University of
Göttingen.

(For the Medical Gazette.)

[Continued from p. 108.]

THERE can be no question that the progress which has been made in the course of the last half century in the distinction or diagnosis of disease, as well as in its treatment, by medicines and surgical operations, has had the effect of saving many lives that would else have been lost. In the beginning of the present century medicine was still without the means of distinguishing one form of disease of the heart and of the lungs from another, so that prescriptions were necessarily written in a great measure in the dark, or medicines were at best directed with a view to the alleviation of particular symptoms, never with the purpose of striking at the root of the evil. At the present time, with the aid of percussion and auscultation, it is admirable with what precision the diagnosis can be established in regard to almost every variety of disease to which the viscera of the thorax are obnoxious. Inflammation of the membranes of the brain, of the lungs, and of the bowels in infancy, had also been little studied until very lately; and being either overlooked or misunderstood, these formidable affections were of necessity indifferently treated, and very commonly proved fatal. The old mode of treating syphilitic diseases was often as fatal in its effects as these maladies themselves.* Aneurisms, which in

former times were almost necessarily mortal, are now and since Mr. Hunter lived almost as certainly treated with success; he who had an aneurism in his ham had scarcely a chance beyond that which amputation of the thigh afforded him: the hand of the master through an incision two inches in length now attains the artery in its course to the disease, passes a ligature around it, and in the great majority of instances the patient escapes with life and limb preserved. Deformities and imperfections, which were formerly the prey of ignorant empirics, have been made the subject of particular study, by men of liberal acquirements, under the guidance of anatomy and physiology, and are now removed and remedied by appropriate operations in innumerable instances. Squinting, which was always felt as so painful an imperfection by the individual, and which also made him incompetent in certain directions as a member of the community*, is now remedied by a simple snip, almost as certainly, and with little more pain than stammering is treated by systematic exercise of the organs of speech.† How numerous the cases of blindness held irremediable in former years, which are now restored to sight!

And let it not be brought against all that has now been said, that new names of diseases are every day appearing as evidences of their increase. Names are still no things. The botanist who should make new genera and species out of mere varieties, would no more enrich the flora of a country, than the nosologist who should raise symptoms and varieties to the rank of particular species, and designate each by a name, would add to the number of its diseases. The number of diseases, happily, has not increased in nature, but in books; classifications of our infirmities, not our infirmities themselves, have increased. It happens, not unfrequently, indeed, that diseases which, from description and at first, appear specifically distinct, are found after more careful investigation to differ but in

* Such statements as the following are as true as they are encouraging:—"Riddled and honey-comb skulls, looking as if they had been eaten of worms and gnawed by dogs, are now, fortunately, rarely to be seen except in the glass cases and drawers of Surgical museums, or in Cheselden's plates;—venerable relics of a past age, out of date, like the silk coat and full ruffles of the contemporaneous doctor. These were the consequences of a profuse abuse of mercury which is now rarely attempted."—*British and Foreign Med. Review*, 1840, vol. ix. p. 240.

* In Würtemberg sixty-seven individuals were declared incapable of the military service in the course of five years, on account of determined squint.—Ecke, op. cit. p. 27.

† It must be allowed that surgery went wrong here. Several unwarrantably severe operations were performed on the root of the tongue, by way of curing stammering, and several lives were lost; but the mistake committed was soon discovered, and the barbarous procedure abandoned.

degree, and to have suffered modification from climatic and national influences—for example, oriental plague, and our own typhus.

If certain diseases be spoken of at the present time as extremely common, and as still spreading, this frequently happens from a fashion in a particular school, or the influence of a single physician. Some persons meet everywhere with diseases of the heart*, others with affections of the spinal marrow, others with derangement of the stomach, of the liver, &c., and then it appears as if humanity were to be put to a new and sore proof; but by and by the prevailing fancy passes, it is recognized as the effect of hypothesis, it has its day, and all returns to the ordinary and usual in sickness as well as in health.

And then if it were granted that particular diseases are now more frequently observed than they used to be, have we any assurance that therefore these diseases are commoner in fact?

Among uncivilized tribes and nations a very large proportion of the more weakly children die in the course of the first year; in civilized communities such children are reared in great numbers, and only fall victims later in life to natural or accidental causes of decay. How can it be said that this or that disease has increased in frequency, when it is acknowledged that a much larger proportion of mankind, by attaining to old age, are made obnoxious to its attacks? Where there are few or no subjects for apoplexy to invade, there are few or no invasions of apoplexy. Civilization can only guard against and abate circumstances that induce disease; it has no power to bestow physical immortality. Precisely in the ratio of the greater mass of life and living energy that presents itself in the civilized world, is the glory of the victory that is won over the multiplied and infinitely various causes which threaten derangement and de-

struction. References to historical and statistical accounts of almost all diseases satisfy us of the truth of this position. Let us select a few of the more remarkable for particular inquiry.

Phthisis pulmonalis.—The frequently asserted increase of this formidable disease*, which so constantly invades in the very flower of life, when the body has attained its growth, and the mind is close upon maturity, can by no means be allowed. The tables of mortality that could alone supply elements for definitive conclusions on the subject, are very far from being extant in even approximative completeness and authenticity.

One of the latest writers on consumption†, who has given a review of the deaths from consumption in London between 1700 and 1821, says:—

The opinion entertained by some authors, that consumption has increased since 1750, originates in the error of taking its *relative* mortality as compared with that from all diseases, instead of its absolute mortality in reference to the population.

And then if the statistical tables of those cities and countries where they have been kept with care for a series of years be referred to, it will be found that, instead of an increase, a positive diminution of pulmonary consumption has taken place. In Stuttgart, for example, fewer deaths from phthisis are recorded year after year‡. In the course of five years no more than three individuals had been found unfit for military service by reason of phthisis pulmonalis§.

The ancients frequently speak of phthisis, and, at the same time, dwell upon its hereditary transmissibility and contagious nature||. But as in the pre-

* According to Bernoulli (Population, p. 308), in the year 1828, 1-9th of the whole mortality of Paris was due to phthisis—1-10th of the males, 1-8th of the females, having sunk under this disease. But this statement is not borne out by the figures of other writers (Vide Clark on Consumption).

† Clark, op. cit.

‡ Between 1787 and 1791, there died of consumption within the precincts of Stuttgart, 773 persons; between 1793 and 1796, 675 persons; between 1797 and 1801, 546 persons; between 1802 and 1806, 475 persons; between 1807 and 1818, 465 persons—ten less in these twelve years, therefore, than in the five years from 1802 to 1806 (Cless, Med. Topography of Stuttgart, p. 69.)

§ Riecke, Contributions, &c. p. 43.

|| Riecke, op. cit. p. 18.

* The Roman gladiators appear to have suffered frequently from inflammatory diseases of the heart, which, as well as affections of the great vessels, were well known to the ancients (Vide Sprengel, l. c., v. i. and ii.) The copious literature which the last ten or twenty years have produced upon diseases of the circulating system is no kind of evidence that such diseases have increased in number and severity; they are now much better known, and more regularly diagnosed, than they used to be.

sent day the term consumption is by no means restricted to signify the decay that attends upon tubercular disease of the lungs, so in former times the word phthisis was obviously used with considerable latitude. The Father of physic, however, condescends upon the period of life when phthisis occurs most frequently, between the 18th and 35th year, an observation the truth of which accords remarkably with the latest statistical results obtained from Berlin, Paris, Edinburgh, Philadelphia, Nottingham, Chester, Carlisle, &c.*

Some countries, from geographical position and endemic relations, appear to be unfavourable to the development of consumption; Egypt, for instance, has been known, from remote antiquity, to be propitious to the consumptive invalid†.

Those countries and districts that are obnoxious to fever and ague are said to suffer little from pulmonary consumption‡. It is possible, however, that the countries from which this inference is drawn owe their reputation rather to the mildness and equality of their climate, to the absence of sudden changes of temperature, well known to try irritable lungs so severely, than to any miasmatic or fever-engendering influences§.

* Clark, op. cit. [The mortality in this country rises rapidly about the age of puberty, more so among females than among males; between 15 and 20, it is half as great again as it was between 10 and 15.—Eng. Ed.]

† Celsus, De Medicina, l. iii., 22. "Quod si vera phthisis est, inter initia protinus occurrere necessarium est * * * apilissime Alexandriam ex Italia itur." Vide, also, Röser on some of the Diseases of the East (in German), Augsb. 1837.

‡ Vide Wells, Obs. on Pulmonary Consumption and Intermittent Fever, chiefly as diseases opposed to each other, in Trans. of a Society for improving Med. and Chirurg. Knowledge, Vol. iii. London, 1812. Also, Blane, in his Select Dissertations; and Hennen's Med. Topography of the Mediterranean. In the West Indies, however, where fever is so fatal, the mortality from pulmonary consumption is very great (Vide Clark, op. cit.).

§ Much evidently depends upon race in regard to liability to phthisis in particular countries or climates: Great Britain is probably the healthiest country in the world—to its own children; to all the coloured races of men it proves a grave within one or two years. In Ceylon, phthisis is extremely rare among the natives; but the blacks very frequently die consumptive in that island. A regiment which, in Scotland, is losing regularly about 4·5 per 1000 from pulmonary disease, transferred to Jamaica, begins immediately to lose about 19 per 1000 from the same cause; transferred to India, it will lose about 11 per 1000 from liver disease and dysentery, and not above 1 or 3 per 1000 from pectoral complaints.—Eng. Ed.]

¶ Many districts of Italy are infected with fever of the intermitting and remitting kind, without being therefore by any means exempt from pulmonary consumption, which appears, in fact, to

be even more frequent and fatal in Italy than in England. Persons in aquatic districts are aware of the necessity of clothing themselves warmly, and thereby probably become less liable to phthisis.—Eng. Ed.

Since the deleterious influences of many handicrafts, such as needle-pointing, knife and fork grinding, brush-making, stone-cutting, water-gilding, have been known, and their causes investigated, means for abating or rendering them ineffectual have been taken, and the mortality because of them has been lessened†.

It may safely be said that no disease ever arrested in a greater degree the serious attention of distinguished medical men than this of pulmonary consumption. The phenomena of tubercular deposition which in the great majority of instances is the first appreciable link in

be even more frequent and fatal in Italy than in England. Persons in aquatic districts are aware of the necessity of clothing themselves warmly, and thereby probably become less liable to phthisis.—Eng. Ed.

* Our friend the late Dr. M'Kinnel knew himself that he was consumptive, that he had a cavern the size of the closed fist in one of his lungs; nevertheless, by leading a most temperate life, only shewing himself abroad during the fine months or weeks of our summers, &c. he lived, for ten or twelve years, a life of great intellectual enjoyment. He even went, for two years, surgeon of a frigate to the coast of Africa, and all the while consumptive.—The distinguished author of several of the most useful works that were ever written in medicine—Physiology applied to the Preservation of Health; On the Treatment of Insanity; On Digestion; &c.—has lived, and still lives, with much enjoyment of existence to himself, with infinite advantage to the world, and all the while affected with true consumption: twenty years since he had first one, and then another, tubercle deposited and softened in his lungs. May he live for twenty years to come, the delight of his friends, and to make the world still more his debtor than it is!—Eng. Ed.

† Very sufficient means are now familiarly known for carrying off the grit and iron-dust of the grinder's shop-dust flues; but strange to say, the workmen themselves object very generally to use them! "they regard every precaution to prolong life with jealousy, as a means of increasing the supply of labour, and lowering wages; they are for 'a short life and a merry one,' and hence, even when the masters are at the expense of erecting the apparatus, these men refuse to use it, and even frequently kick it down, and break it under their feet." Second Report Children's Employment Commission, Evidence, 563.—Eng. Ed.

the chain of morbid processes, have been so thoroughly investigated, the circumstances under which the deposit takes place, and those that favour its softening and elimination are so well understood, that reasonable hopes may be entertained of our being one day in a condition first, to prevent the formation of the inorganic mass, and then to secure its absorption or removal by a way less hazardous than that of internal softening, and ulceration of the surrounding structures*.

Conclusions from bills of mortality, the documents hitherto relied on by statisticians and medical men for data, also require to be drawn with much foresight; medical science is not yet at such a point of perfection with the entire mass of practitioners and the public, as to make it quite certain that every disease which proves fatal is correctly named. Several diseases of very different nature are entered under the common title of consumption or decline; and it is always doubtful whether those that figure as *disease of the chest*, as *chronic catarrh*, as *hæmoptysis*, &c., were or were not proper tubercular phthisis.

Scrofula, a disease from which the youthful in especial suffer, may safely be said to be on the decrease rather than the increase; the circumstances which favour its production are certainly less influential than they were, and are likely to become every day less and less so. The better houses in which the mass of the community now dwell, the greater attention to cleanliness, the regular and cheap supply of wholesome and easily digested food† all conduce to render the disease

less frequent than it used to be, and to restrict its ravages when it does make its appearance. A smaller proportion of amylaceous and a larger allowance of animal food, warm clothing, a dry house, exercise in the open air, and the use of the tepid or cold bath according to the season, are all so many powerful means both of preventing and of curing scrofulous disease.

The older medical writers describe scrofula accurately, but their treatment was not always well directed; they were too much disposed to look upon the disease as an external and local evil, and to bring the enlarged glands which characterize it to suppuration. Among the multitude of anti-strumous medicines and means, superstitious observances and specific remedies, we have now come to the conclusion that the proper curative treatment of scrofula consists in dietetic and general hygienic measures; and it is certain that this conclusion will not be without excellent effects in times to come. Here, as elsewhere, it is science going hand in hand with civilization that can alone make known the true ways and means of living aright, and compel observance of them in the most fit and proper manner, according to individual wants and peculiar circumstances.

Rickets is certainly a very old disease; the Arabian writers point to it the evils of destitution and the blessings of abundance than any other member of the body politic. He knows that disease follows want as the shadow follows the substance; and that health is no less inseparably connected with cheap, abundant, and wholesome food. He were therefore no true priest of Æsculapius who should fail upon every occasion that offered to lift up his voice, and urge upon legislators the necessity of removing all restrictions upon commerce in articles of human sustenance. The soil of England is not now extensive enough to grow food for its inhabitants, whether in grain or cattle; shall they continue to be half-fed, and made obnoxious to disease, as they are under the present system of our corn and provision laws, or shall they be suffered to barter the products of their industry for the food they want in the market of the world? These are the questions, and surely there is but one possible answer to them. It is as one of the guardians of the public health, not as a politician, that we speak here. It may seem matter of indifference to the layman whether a labourer shall have 12 or 14 ounces of hydrocarbonaceous matter in the shape of food each day for the supply of his corporal wants; but the physiologist knows that the steam-engine will no more do the work represented by 14 lbs. of fuel with 12 lbs. than will the animal or human body do the work of 14 ounces of food with one drachm less than that quantity. The labour enforced with a single grain of food less than the effort requires, that grain is supplied by the living solids, and a drain of this kind continued, the solids shrink, become deranged or disorganized, and disease and death soon settle the question.—*ENO. ED.*

* The interesting researches of Dr. Baron on this subject deserve particular notice. It is easy by shutting up animals in damp and dark places, and supplying them inadequately with indifferent food, to bring about tubercular depositions into many of the organs—the lungs, the liver, &c. These animals thus diseased, however, have only to be brought into good air, to have opportunity of taking exercise, and to be abundantly fed with good and nutritious food, in order to recover rapidly; the tubercular depositions which had taken place are removed, and perfect health is regained. A French physiologist further found that animals placed in circumstances known to produce tubercles, escaped if supplied with bread having a certain proportion of carbonate of iron mixed with it, &c.—*ENO. ED.*

† Our excellent author does not live under the shadow of a corn and provision law, as we do in England, or he would write differently. It is not for the medical practitioner to meddle with party politics, but as he knows more of the poor than any one else, so is he better informed on

under the name of the gibbosity or crookedness that occurs from fever*; it was farther observed, in the course of the sixteenth century, in Holland and Switzerland†; and was so admirably described by an English writer in the succeeding century‡, that it has retained the special title of "the English disease," in Germany, up to the present time. There can be no doubt of this disease having, like scrofula, become rarer than it used to be, and from the same causes§. Deformities of limb from rickets are comparatively rare, especially among the middle and upper classes; and if we observe establishments for the treatment of this class of diseases springing everywhere, and the press teeming with treatises upon the subject, we are not therefore to imagine that they have in fact become more frequent than they were: the active competition among professional men, the vastly increased number of writers upon every topic, suffice to account for the greater attention which deformity excites, without supposing that it is of more frequent occurrence now than formerly. The treatment of this class of complaints has, indeed, but lately been rescued from the hands of ignorance and empiricism; evils that were once borne in silence are now proclaimed; men are no longer content with health—they desire, in addition, beauty and vigour.

At the very head of the list of sore evils which long afflicted, and still to some extent afflict, mankind, must be placed *syphilis*. Without entering, in this place, upon the question as to whether the disease was known to the ancients||, and others of minor moment, this much may with assurance be said: that, prevailing for a succession of ages with great severity, perhaps no disease that ever existed carried so many evils in its train, or spread so irresistibly and extensively over the surface of the habitable globe. The innocent as well as the guilty were its victims; the unconscious infant, the babe unborn, were not beyond the reach of its poison. All

the means which earlier times essayed for its control proved fruitless, or seemed rather to add to the evil; a fateful calamity appeared to have overtaken mankind, to have infected the sources of his being, and to threaten the very existence of the species. This disease has made good its footing in the world; it still exists among us; but how, or in what direction, have not the influences of civilization and the discoveries of science, circumscribed its ravages, its power, its effects? In former times extremely dangerous, it is now, comparatively, a trifling malady. In the same measure as knowledge of the intimate essential relations of this disease to the forces of the organism, and to the virtues of medicine extended, have the morals of states and smaller communities increased: all circumstances, in a word, having conspired to circumscribe its attacks, and to render them inefficient when they occurred, it has now lost most of its importance both to the individual and the state. It is not to be denied, indeed, that the way up to this point has been traced with much suffering; the very remedy that was long held indispensable in the treatment frequently did almost as signal mischief to the general health as the disease itself. But it has for some time been recognized that the injury done was rather from the abuse than the right use of the remedy; and then, that no specific means of cure whatsoever were requisite, that heroic remedies of every kind can be perfectly well dispensed with. It was first observed that the disease presented itself with a milder aspect in the warmer countries of the earth,—in Egypt for example,* and that there it frequently yielded to the unaided powers of nature. In the north or colder climates, however, it was still thought that more active measures were requisite; but this presumption has also disappeared, and since practitioners discovered that the chief therapeutical indications were to be directed to the skin and mucous membranes, and that mercury was by no means indispensable, the disease itself has become not only more simple and more tractable, but the organism after its removal has been left more free from consequences of every kind.

The more intimate knowledge now possessed of the *syphiloidea*, the *radesyge*

* Serapion the elder, vide Sprengel, l. cit. v. 3, p. 381.

† Sprengel, ut sup. v. 4, p. 509.

‡ Gilsson, De Rachitide, Lugdun. Batav. 1671.

§ How frequent the disease still is, however, may be imagined from Riecke's statement (Contributions, &c. p. 44), that in Würtemberg alone there are 33,000 persons affected with deformity of the bones of the chest.

|| Upon this hypothesis, see Rosenbaum's History (in German); Halle, 1839; p. 461.

* Ræser, l. c.

and spetalska of Norway, the sibbens of Scotland, the scarlievo of the Adriatic shores, the morbus crureus of the coasts of the Black Sea, the rose of the Asturias, the Aleppo pustule, the yaws of the West Indies, &c. excite doubts as to the relationship of many of these diseases with syphilis.

These insidious and strange diseases, once acknowledged to be so formidable, have for the major part been long brought under the rubric of ordinary affections, amenable to art, and to be familiarly and successfully dealt with by every village practitioner. The friend of humanity may, indeed, look forward with much confidence to their gradual decrease and final extinction at no very distant period: the higher demands of morality, the growing attention to the general sanitary condition of communities, the better police that is extending over the world, backed by the ceaseless efforts of science to arrive at a knowledge of causes, and to overcome vicious customs and absurd prejudices, all give us assurance that these, among other ills, will one day become matters of historical record.

Even as these three, the most deadly and far spread of all the affections of humanity, cannot only not be charged upon civilization as among the number of her offspring, but are much rather warred against with the whole of her energies, so it is with almost all other maladies, inasmuch as the representatives of civilization, science, art, and morals, still wage a more open or more covert but ceaseless warfare with every one of them. The time may come,—on scientific and abstract grounds it ought to come,—when the great majority of mankind, escaping the host of evils in the shape of sickness that have still beset their path, may

“Live till like ripe fruit they drop
Into their mother’s lap, or are with ease
Gathered, not harshly plucked, for death mature.”

To set this matter in a clearer light, it will be instructive briefly to review some of the more remarkable forms from the several divisions of pathology.

The civilization of the ancients had attained so high a point that we still contemplate with wonder and admiration the remains of their architecture and sculpture, the mighty works of their poets and historians, as monu-

ments of a bygone more beautiful world than that which we now inhabit. All the appliances and arrangements of their public and private lives formed such a tissue of varied artistical and sensual enjoyment, that the reproach of over-refinement, which is frequently made against the present age, is probably unfounded.

But granting that in our world of to-day we want the simplicity and grandeur of thought that distinguished the ancients, that we rather inherit their exaggerated desires, their affections, their passions, and have only associated these with the conceptions and exigencies of another order of things, it must still be allowed that in reference to *nervous diseases*—which, like the strings trembling after the chord struck by a powerful hand, remind us of the foregone excitement—no new form of derangement has been noted. On the contrary, when we recur to the narratives of antiquity, and contrast the pictures which they present with those we have now before our eyes, we see that the circle of nervous diseases has been narrowed rather than enlarged.

Even within the observation of the present race of medical men—a mere span in time, and scarcely to be named along with the historical epoch—one very dangerous form of nervous disease, *nostalgia*, or home sickness, has almost disappeared. How frequently, in days but recently gone by, did this painful and destructive longing seize upon our mountaineers and natives of sequestered hamlets, separated from their homes! and how rarely is the name of *nostalgia* now heard! The once isolated valley is now the seat of active traffic; its inhabitant is brought into contact with the rest of the world; the red man of the Indian woods now visits the Switzer on his mountains; the Switzer seeks out the red man under the shadow of the primeval forest; the rapid means of communication we now possess in our stage coaches, our railroads, and our steam ships, have put an end to the distressing sense of isolation, to the chill of loneliness experienced by the stranger; letters from home reach their destination with magical rapidity and security; and the feeling that every passing thought can be fixed, and sent as it were upon the wings of the wind, to the spot whither the heart tends,

leaves no room for despair, scarcely for uneasy longing to enter.

Our modern facilities of travel do more than this; great evils are not alone worthy of consideration; *hypochondria* and *hysteria* are less frequent than they were, mainly, as it seems, through the taste for travelling; they are mostly soon put an end to by an excursion for a few weeks. Travelling is indeed a powerful remedial means in these forms of disease, as well, apparently, in virtue of the passive and more active exercise it implies, as of the new mode of life that is forced upon the invalid, of the necessary participation in foreign feelings, of the ceaseless afflux of new and amusing impressions which there is no avoiding,—all these soon force the sick man to forget himself, and he feels new life infused into his heart through contact with the world around him.

In so far, also, as with little trouble, and less cost than formerly, that place of residence may now be selected which the requirements both of body and mind seem to indicate, is life, in many instances, prolonged. The increase of vigour which the whole system, in some cases, experiences from a change of residence, or of climate, sometimes exceeds all calculation.*

The more serious organic derangements that sometimes complicate hypochondriasis and hysteria, are now diagnosed with much greater accuracy than heretofore; every respectable practitioner is now acquainted with the mode of examining the abdominal organs by palpating, percussion, &c.; and their true state ascertained, the needful medicines are presented with something like assurance that they are well chosen; they are at all events prescribed with a definite object in view.

Whoever should conclude that hypochondriasis and hysteria were rare diseases in former times from the unfrequent mention made of them in the writings of our older authors, would err egregiously; the diseases are there described, but under other names, such as *cholera sicca*, *inflatio lienis*†, &c.

* Rush, in his *Natural History of Medicine among the Indians*, estimated this influence very high; he says, "A Frenchman outlives an Englishman in England; a Hollander prolongs his life by removing to the Cape of Good Hope; a Portuguese gains fifteen or twenty years by removing to Brazil."—*Vide* his *Medical Inquiries*, Vol. I.

† Sprengel, *op. cit.* i. 488; ii. 292, *ἀσθμία*,

The disease called *St. Vitus's dance* is another form of nervous disease which undoubtedly existed in former times, but which is comprised under a common title in the account of other diseases. As this is a complaint which mostly occurs in those years when the body is acquiring its full development, and as the changes which the system undergoes in its progress to maturity, are every year made more particularly an element in our medical studies, and further as the physical education of youth is ever more anxiously considered, it seems that *St. Vitus's dance* must of necessity become rarer and rarer; indeed, fewer cases of the malady now come under medical care than formerly.

The *dancing mania* of the fourteenth century appears to have been an immediate effect of the dissolution of all ties, public and private, consequent upon the progress of the frightful epidemic known under the name of the black death. Multitudes were seized, as by a pestilence, with a kind of infernal disposition to wander through the country in motley bands, and to dance till they fell down exhausted, being frequently attacked at the same time either with simulated or actual convulsions. Except those who, carried away by the spirit of imitation, joined these dancers, the bands appear to have been mostly composed of persons who lived upon public charity as long as it could be extorted; it was only, in fact, when the springs of charity had been exhausted, and the sense of decency began again to make itself heard, that these dancers were led back to the rational tranquillity of civil life. With a state of things such as now exists, it is scarcely possible to conceive the recurrence of such an epidemic as this. And yet it must be confessed that something similar has lately been witnessed in the preaching mania of Smaland, a province of Sweden; but how speedily was this strange commotion put an end to by the concurrence of all the reasonable heads in the district!*

ib. p. 53, *morbus mirachialis* s.; *mirachia*, ib. p. 368, 396, 431. Under the rubric *Lethargy*, Morris, in his *Observations on the Past and Present State of the City of London*, 1751, includes the hypochondriac and hysteric passions.

* Some Account of the Crying Voices, or Preaching Disease, in Smaland, in the years 1842 and 1843, by an Eye-Witness, Leip. 1843.

Can this be an extension of the unknown-tongue foolery, which we had in London some few years ago? It looks very much as if it were. The

Catalepsy, since its reality as a special form of disease has been questioned, instead of being now an object of nosology, is rather one of history*.

The peculiar convulsive disease known under the name of *rhapsanism*, and occasionally, from its extraordinary symptoms, of the convulsive tragedy†, only shews itself, at this time, in districts where no measures are taken to prevent the development of ergot or spur-corn. The causes of the disease are now perfectly well known; and an improved system of agriculture, the grand feature of which consists in thorough draining, seems competent to prevent its occurrence. In wet seasons, when the bread flour is apt to be contaminated with the poisonous fungus that constitutes spur in wheat and rye, continental governments usually caution the public against the mischief that is apt to accrue without proper care in separating the diseased from the sound grain.

Paralysis, especially of the lower extremities, is one of the diseases so commonly seen at the present day, that it were probably wrong to deny that it is not more frequent now than it used to be‡. But as it seems very probable that political changes, and the worry, and excitement, and misfortunes to individuals, that are inseparable from them, added to the hardships of the military life during actual warfare, had

a large share in the production of this kind of palsy*, so let us trust that continuing peace, and the security which is now felt by the industrious citizen, will restore the balance, or even put something into the opposite scale, and make paralytic affections rarer instead of more frequent than they were before.

Neuralgia, or painful nervous diseases, particularly tic douloureux and angina pectoris, have certainly been very frequently met with since the beginning of the present century; still it is difficult to say anything positive as to their increase; we are not sure whether certain diseases which are described by writers our immediate predecessors under such titles as a "spasmodic convulsive affection of the lips" (Hoffman), as a "trismus dolorificus" (Sauvages), &c. were the same as the Fothergillian tic douloureux. The Arabian physicians frequently speak of "painful spasms of the face‡," and one of them§ recommends remedies or counter-irritation to be applied in the neighbourhood of the place of origin of the affected nerve. Many distinguished personages of antiquity appear to have died of angina pectoris, so that we have no authority for believing it to be commoner now than it was in former ages of the world.§

[To be concluded in our next.]

DR. SHEARMAN ON THE TESTS AND ANTIDOTES OF ARSENIC.

To the Editor of the Medical Gazette.

SIR,

I HAVE for a length of time felt surprised that the judges in our criminal courts should often admit what I think must be held as indecisive evidence of the administration of poison. During the late assizes two cases occurred where arsenic was most positively sworn to, merely from what is commonly called the reduction test, i. e. the production of a metallic ring of what is considered arsenic, in a bulbéd tube. A few weeks ago, a paper of mine on this subject was read at the Sheffield

* Blane observed that paralytic affections were more frequent in hospital than in private practice.

† For instance, Rhazes, in Sprengel, l. c. ii. 397, 402; Avicenna, ib. 434; Albucasis, ib. 451.

‡ Musae, ii. in Sprengel, u. s. ii. 448.

§ Among the number Seneca (vide his 54th Epistle, and Sprengel, v. 602), and the Emperor Alexius Comnenus I. (Sprengel, ii. 324.)

unknown tongues had of course some advocates and believers among us; but they were few in number, and as the reasonable heads here, as in Sweden, would not listen to the gibberish which the unknown tongues uttered, they soon ceased to wag. The grand mischief that they did was killing poor Edward Irving, the single-minded, the enthusiastic, the good, but alas, not the reasonable or strong-minded!—ENG. ED..

* Buraerius, Institut. § 159, and Cullen, Nosol. Method., conceive it to have been deception, [a conclusion of these great men in which we acquire the greater confidence, seeing that, since their time, the subject of catalepsy is a favourite one with mesmerists, phreno-magnetizers, et hoc genus omne of compound dupes and impostors.—ENG. ED.]

† Vide Wedel, De Morbo Spasmodico-epidemico Maligno in Saxonia adhuc Grassante, Jene, 1717.

‡ Heberden, nearly half a century ago, remarked that paralysis and apoplexy had become more frequent since the beginning of the 18th century; and he is disposed to ascribe the increase to the prevailing use of hot drinks and spirituous liquors. In his Observations on the Increase and Decrease of Diseases, Lond. 1801, p. 37, he says, "gradually and constantly increasing, it is now above double what it was an hundred years ago." In my work on Paralysis of the Lower Extremities I also remark on the greater comparative frequency of this affection, and Bellini had already done the same thing before me. (Vide Medical Trans. pub. by Royal College of Physicians, vol. vi.)

Medical Society, and as I feel assured that you will agree with me in thinking the matter of great importance to professional persons who are called upon to give evidence in courts of justice, perhaps you will honour me by inserting the following abstract of that paper in your very valuable journal. If, as I think I have shewn, the only *definite proof* of the existence of arsenic is the production of the *crystals*, both of the metal and the oxide, then it would be right that unless these crystals are produced to the jury, the prisoner should have the benefit of the doubt that must hang over the conclusion in regard to the presence of arsenic at all; for it is certain that the metallic ring, as shewn in the reduction test, can be produced by other metals besides arsenic. These crystals are very easily produced from the most minute particle of arsenic by any one at all acquainted with chemical manipulation: and of course no other ought to be called upon for an opinion upon such a subject, and where the liberty, or the life it may be, of an innocent prisoner is involved.

I am, sir,

Your obedient servant,

EDWARD JAMES SHEARMAN, M.D.
Member of the Royal College of Physicians, &c.
Rotherham, April 25th, 1844.

On Arsenic as a Poison: its Tests and Antidotes.

In order to prove the existence of arsenic, in a court of justice, we should be enabled to show the following facts so satisfactorily, that a jury may not only *see*, but *perfectly understand* them.

1st. The metal should be produced either from the contents of the stomach, intestines, or urine, if the patient should survive: or, if dead, from these and some part of the body.

2d. We should be able to prove that the animal substances experimented upon were the excretions and parts of the patient's body only; *unmixed with any other matter*.

3d. We must also prove that the tests we use to shew the existence of arsenic *have not a particle of arsenic in themselves*. And this requires great caution, because a skillful advocate might make a guilty prisoner appear innocent, owing to this omission.

4th. As *antimony, bismuth, tin, zinc, lead, tellurium, cadmium, selenium, and*

potassium, sublime in a somewhat similar manner to *arsenic*, and may be mistaken for it, it is absolutely necessary to guard against such a mistake.

The most common mode of obtaining arsenic from an organic solution is that of Dr. Christison; in which he gets rid of the animal matter by boiling for half an hour in distilled water with strong acetic acid—which often precipitates the casein, and renders it sufficiently pure: if not, the solution should be neutralized by potash or ammonia, slowly evaporated to dryness, redissolved in distilled water, filtered when cold, and then evaporated several times again. This eventually produces a solution free from animal matter. With the ammoniacal nitrate of silver this gives a *lively yellow precipitate*—the *arsenite of silver*: with the ammoniacal sulphate of copper, an *apple or grass-green precipitate*—the *arsenite of copper*: and with sulphuretted hydrogen gas (previously acidulated with acetic acid) it throws down an abundant *yellow precipitate*—the *sulphuret of arsenic*. This sulphuret should be collected on a filter, dried, mixed with black flux, or freshly ignited charcoal, introduced into a bulb tube, and properly heated by a spirit lamp, when a *brilliant polished metallic ring of metallic arsenic* will be sublimed all round the tube. *This is called the reduction test*. This metallic ring of arsenic should then be oxidized by exposure to the heat of a spirit lamp in atmospheric air; when *octohedral crystals of arsenious acid, with triangular facettes*, will be deposited on the upper part of the tube, which may be easily seen with a tolerably good microscope.

In Marsh's test, where hydrogen gas is generated from zinc, sulphuric acid and water, and the suspected substance is added in solution, arsenic having such an affinity for hydrogen quickly combines with that gas and forms arseniethed hydrogen, which being ignited, metallic arsenic is deposited on porcelain or glass, and may be seen in *rhomboidal crystals* with a powerful microscope. The objection to this test is, that we are *obliged to use zinc which often contains arsenic*: and although it shews the most minute quantity, how can we swear, after the first layer of zinc is oxidized, that there may not be arsenic in the next? for arsenic runs in the veins of the ore.

In Professor Reinsch's test, modified by Christison, we mix the suspected matter with distilled water, add zij. of pure hydrochloric acid to every eight ounces of fluid, immerse a very thin and bright copper plate, and boil for half an hour, when the whole of the copper plate will be coated with arsenic. By cutting these plates into chips, and exposing them in a tube at a low red heat over a spirit lamp, arsenious acid will be sublimed in *octohedral crystals with triangular facettes*, which may be rendered more distinct by turning out the chips, covering the tube with the finger, and chasing the oxide up and down the tube over the lamp.

A most ingenious, scientific, and elegant method of obtaining arsenic has lately been introduced by Robert Ellis, Esq. of University College. He has discovered that the oxides of copper have such an affinity for arsenic, that by merely passing arseniетted hydrogen over them, a double decomposition takes place: caloric is given out; the oxygen of the copper uniting with part of the hydrogen forms water, which is seen in the process; the arsenic of the arseniетted hydrogen uniting with the copper forms arseniuret of copper—the remaining hydrogen being set free. This arseniuret of copper may be easily sublimed in a glass tube, when the whole of the arsenious acid will be deposited in *thick brilliant clusters of octohedral crystals on the tube*. The objection urged against Marsh's apparatus will equally apply to this—that of being obliged to use zinc for the generation of hydrogen.

The *cleanest and safest* mode of detecting arsenic is by *decomposing distilled water by galvanism*, to which is added the suspected solution, and pure sulphuric acid: collecting the hydrogen from the negative pole or zincode of Smee's battery, igniting it, and examining the stain left in a glass tube, open at both ends. If there is the smallest particle of arsenic, the hydrogen will unite with it; and you then have a stain of *metallic arsenic with rhomboidal crystals*, which you may then oxidize into *octohedral crystals*; collect, dissolve in water, go through the fluid tests, reduce the sulphuret in a tube, and sublime into arsenious acid again. This is the *most delicate test known*, and perfectly free from the charge of using any substance in which arsenic can exist.

The most likely substance to be mistaken for arsenic by any of these tests is *antimony*, because *antimony sublimes into the same kind of crystals as arsenic*. But by attending to the following rules the two substances may easily be distinguished. *Metallic arsenic sublimes into rhomboidal crystals at a heat of 356° without liquefying. Arsenious acid sublimes at 380° into octohedral crystals. Metallic antimony sublimes not under 810° , and on cooling, acquires a highly lamellated texture, and yields octohedral crystals like arsenic, which are insoluble in water; whereas the octohedral crystals of arsenious acid are very soluble, and which solution may be tested by the three fluid tests.*

In the reduction test with sulphuretted hydrogen gas, it should be *carefully remembered* that the *sulphurets of antimony, tin, selenium, cadmium, and tellurium*, have nearly the same yellow colour, and are deposited in the same manner as arsenic, and when reduced to their metallic state with black flux, they not only give an appearance so much like arsenic, that it requires a very practised eye to distinguish each, if even that be possible; and tellurium and cadmium also exhale a garlic odour like arsenic.

The question then comes,—*how can a witness swear most positively, that a substance is arsenic and nothing else? and how can he convince an unsentient jury of that fact?* I think only in the following manner.

1st. *By producing the metal, and showing its crystals.*

2d. *Reducing it to the oxide, and showing its crystals.*

3d. *From these crystals going through all the fluid tests.*

4th. *Reducing the sulphuret again to its metallic state, then to the oxide, and again going through the fluid tests.*

If this be shown clearly with all the before-mentioned tests, it will be impossible for any advocate to mislead a jury.

The only antidotes which have been discovered for arsenic are the *moist hydrated per-oxide of iron*, and the *moist hydrated per-sulphuret of iron*. I have lately given dogs and rabbits large doses of arsenious acid in solution and powder, and immediately afterwards large doses of the moist hydrated per-oxide of iron, and then killed them within a short time. The stomachs have shown minute patches of inflam-

mation, but no arsenious acid could be detected by Reinsch's method, the copper plates having merely a scaly deposit of iron upon them; nor could arsenious acid be detected in any other way. This is a strong presumption that the whole of the arsenic was reduced to its metallic state.

In the 1st vol. of the LONDON MEDICAL GAZETTE for 1841-2, page 116, is a communication from the celebrated Dr. Beck, containing an account of no less than 29 cases of recovery from poisoning by arsenic, by the prompt use of the moist hydrated per-oxide of iron, in the human species; and I could point out more which I have observed related in the journals. So that from the results of my own experiments, and the accounts I have read of the successful use of the moist hydrated per-oxide of iron as an antidote to arsenic in the human subject, by many practitioners, I am induced to place great reliance on this substance.

The last edition of the Edinburgh Pharmacopœia (as well as Dr. Beck in the above-named journal) gives a very good formula for preparing this antidote, under the name of "*Ferrugo*." It can be kept good and fit for use in stoppered bottles, for any time, if covered with water. A table-spoonful should be given every five minutes in plenty of water, to an adult, and a dessert-spoonful to a child, until relief from the urgent symptoms is obtained.

Dr. Golding Bird suggests that hydrated per-oxide of iron may be extemporaneously prepared by adding one ounce of liquor potassæ to half an ounce of tincture of sesquichloride of iron.

REPORT OF

FATAL DISEASES AND MORBID APPEARANCES

OBSERVED IN THE POST-MORTEM EXAMINATIONS MADE AT ST. GEORGE'S HOSPITAL DURING THE YEAR 1843.

BY HENRY LEE, Esq.
Formerly House-Surgeon to St. George's Hospital.

(For the London Medical Gazette.)

[Continued from p. 158.]

DROPSICAL AFFECTIONS*.

In twenty-six cases death was ac-

* When the supposed cause of death was discovered in the thorax or abdomen, the head was frequently not opened. The cerebral affections are therefore not included in this account.

companied by some form of dropsical effusion, which, in some instances, appeared the immediate cause of dissolution; in others, the effect of the organic disease which produced it.

TABLE SHEWING THE NATURE OF THE AFFECTION, OR PARTS AFFECTED, IN 26 CASES OF DROPSY.

	No. 1.	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	23	24	25	26	In 11 cases
General anæmia	5
Œdema of lower extremities only	11
Effusion of serum into pericardium	17
Effusion of serum into pleura	17
Effusion of serum into peritoneum	16
Hypertrophy of left ventricle	2
Vegetation on mitral valve of heart	11
Other disease of heart	5
Disease of aorta	10
Disease of lungs	15
Disease of liver	20.
Disease of kidneys	

— Indicates that the circumstance mentioned in the margin was present in the case under the number of which it is placed.

The preceding table is intended to represent the different parts which were found affected, and the various combinations of organs diseased, in the

different instances. It will there be seen that in the twenty-six cases

The heart was diseased in 11 instances

„ lungs in 10

„ liver in 15

and the kidneys . . in 20.

*General anasarca** presented itself in eleven instances, in all of which, with one exception, two or more organs combined to produce the disease.

The heart was here diseased in 5 cases

„ lungs in 5

„ liver in 4

and the kidneys . . . in 9.

Hydrothorax.—Effusion of fluid into the pleural cavity, not accompanied by general anasarca, occurred in seven instances, in three of which there was also some effusion into the abdomen.

The heart was diseased in 4 cases

„ lungs in 4

„ liver in 4

and the kidneys . . . in 6.

The left ventricle of the heart was hypertrophied, independent of other affections, in six out of the seven cases. In one instance, where there was little other organic disease, the muscular structure of the left side of the heart had become peculiarly firm and elastic; when a detached portion of it was bent, it immediately resumed its former position, and a section presented a peculiarly distinct and prominent outline of the columnæ carneæ.

Ascites occurred alone, or accompanied by œdema of the lower extremities, in five instances, in all of which the liver was diseased, and in two the kidneys were also affected. The situation of the right lobe of the liver was in one of these cases occupied by a dense white cyst, coated upon its internal surface by a white, gritty deposit; in the cavity of the cyst were contained numerous gelatinous layers, apparently the remains of hydatid cysts, floating in a fluid of the colour and consistence of cream. There was no portion of the right lobe of the liver remaining.

FEVERS†.

Four cases of scarlet fever were examined after death: the lungs in all were congested and in one instance partially condensed. The spleen was twice found softened, and

* One case of general anasarca and diseased kidneys, complicated by extensive ulceration of the large intestines, is not included.

† In four cases of fever the body was not examined.

congested, and once of very large size, much congested, and as firm in structure as the liver. This occurred in a boy three years of age. The fauces retained indications of inflammation in three instances; in one of which a quantity of pus and lymph was found in the sub-mucous laryngeal cellular tissue, as well as on the outside of, the thyro-hyoid ligament.

Seven other cases of fever were examined, of which the intestines were found inflamed in four, and ulcerated in three. In one instance the ulceration had extended through all the coats of the small intestine, leaving a small round opening, closed externally by a firmly adhering layer of lymph; the fluid contained in the peritoneal cavity was of a brown colour and peculiarly offensive odour: of the seven cases, the substance of the lungs was inflamed in three, and congested in two. In one instance the mucous membrane of the lungs alone was affected. The membranes of the brain were twice found inflamed.

In one instance, where petechial spots remained upon the legs after death, the lungs and kidneys presented, scattered throughout their structure, numerous white, isolated granules; these were all about the same size, less than a line in diameter, and were each surrounded by a narrow circle of livid congestion.

Another case is recorded under the head of fever, in which considerable effusion of serum was found in the cavity of the chest, accompanied by deposit of lymph in the substance of the kidney, and some purulent effusion between the kidney and its capsule.

SECONDARY ABSCESSSES.

Secondary abscesses were met with in twelve fatal cases in all; four of which have already been mentioned under the head of compound fracture. In two cases of fracture of the spine, secondary abscesses occurred; in the anterior mediastinum and lung in one; and in the posterior mediastinum and cellular tissue around the kidney in the other. In four instances they succeeded amputation, and in one followed an abscess over the knee communicating with the joint, and exposing the patella.

The remaining case of secondary abscess was one in which the cellular tissue surrounding the transverse portion of the duodenum was occupied by a collection of ill-formed

pus and lymph mixed with a quantity of cheesy matter: from this point the cellular tissue was infiltrated with purulent fluid in every direction; the supuration had extended anteriorly between the layers of the mesentery, to the left along the pancreas, and upwards behind the peritoneum nearly to the under surface of the liver. In the substance of the liver were found in various situations clusters of veins filled with purulent fluid more or less tinged with bile. In several of these the pus could be propelled along the veins by pressure, but in others the veins were lined by a layer of lymph, which, confining the pus more or less perfectly, formed as it were so many small abscesses. The coats of the duodenum in contact with the purulent effusion were observed to be remarkably thin.

In the twelve cases, the lungs were the seat of the secondary abscesses in ten, the liver in three, the spleen in one, and the kidney in one. Deposit of matter was also found in the gastrocnemius muscle in the one case, and of the sartorius in another. In three instances the synovial membrane of the knee-joint was distended with purulent fluid.

In all these cases, with the exception of the one above related, the primary disease had originated in, or involved, some portion of bone*. In former years it has been observed that the osseous system has been involved in a similar large proportion of cases in this disease: thus of seventeen cases of which notes are preserved, occurring in the years 1841-42, the osseous system was implicated in fourteen instances. If

we add together the result of the three years, we have twenty-five cases in which secondary abscesses followed or were accompanied by disease of the bones; and four in which they were not.

The number of cases in which secondary abscesses occur appears to vary very much in different seasons and years. Thus, of twenty-five cases of compound fracture occurring during parts of the years 1840-41, secondary abscesses occurred in eight instances, while in the year 1842, of seventeen cases of compound fracture, secondary abscess followed in one instance only.

Diffuse cellular Inflammation.—Diffuse cellular inflammation, arising spontaneously, or from slight injury, was in eight cases the apparent cause of death: in three of these it was traced from the neighbourhood of the rectum into the pelvis, extending in one instance to the anterior surface of the aorta, and in another following the course of the ureter to the kidney: the cellular membrane of the leg was the seat of the affection in two cases, and in one was accompanied by the secretion of a very large quantity of purulent fluid into the peritoneal cavity. The cellular membrane of the back, of the posterior mediastinum, and of the side, were the parts affected in the remaining cases: some oval masses of organized lymph were found deposited in the right lung in one of these instances.

Abscess.—The first case of fatal abscess which presented itself was one in which the transverse portion of the colon, and the anterior margin of the left lobe of the liver, were firmly united to the anterior parietes of the abdomen. Between these parts and the anterior surface of the stomach was a large quantity of fetid pus, maintained in its position upon either side by adhesions. An ulcer, extending through all the coats of the stomach, existed at the upper part of its anterior surface. The opening in the peritoneal coat was of the size of a large pea, and although partially closed with lymph, appeared to have allowed the escape of some of the contents of the stomach into the abscess.

Thirteen other cases of fatal abscesses occurred, besides those already enumerated under the heads of scrofulous disease, and secondary deposit. In six cases the disease originated in disease of the lower dorsal or

* Mr. Hunter observes that the ulcerative inflammation is always preceded by the adhesive inflammation, which, he adds, is established for very wise purposes; for "whenever the ulceration has proceeded beyond the adhesions, there the matter will come into unadhering parts; the consequence of this will be, that the fluid or matter will diffuse itself in the cellular membrane of the part, and from thence over the whole body, as in erysipelatous inflammation; but to prevent this effect the adhesive inflammation takes the lead of the ulceration." The same reasoning which Mr. Hunter uses with regard to the soft parts of the body is doubtless equally applicable to the osseous system, although the different processes may be here carried on in a more tardy manner. If the adhesive inflammation does not occur when the cancellous structure of the bone is exposed to the contact of purulent fluid, the pus may become diffused in the interior of the bone, and it is difficult to conceive in what manner it could be removed when it has once spread beyond the limits of the adhesive inflammation, except by the process of absorption.

lumbar vertebrae; and in three of those instances the structure of the bone was rendered much firmer than natural. In another instance the abscess made its way from the hip-joint through the acetabulum, into the pelvis, and thence descended below Poupart's ligament.

In one patient both ovaries had become the seat of abscess, and the uterus consequently firmly fixed in the pelvis by adhesions: on the right side the sac of the abscess was flaccid, and contained some offensive dark-coloured fluid: it communicated with the rectum by two oval ulcerated openings. On the left side the sac of the abscess was distended, and the pus which it contained was of its natural colour and appearance.

Senile Gangrene.—Senile gangrene proved fatal in two cases. In the first, ossification of the arteries had taken place to a great extent: in the second, the lower portion of the aorta and its bifurcation were chiefly diseased. In this case, the aorta below the origin of the inferior mesenteric artery was irregularly dilated to about three inches in diameter. The internal coat was thickened, inelastic, and ulcerated in various situations; the ulcerated portions being covered with firmly adhering coagula of blood. A considerable cavity existed between the internal and middle coat, filled with a pulpy-brown semifluid substance mixed with a gritty deposit.

Inflammation of Lungs and Pleura.—Nine cases of inflammation of the lungs and pleura unconnected with tubercular disease proved fatal. In four instances the pleura contained pus, and in one a communication existed in the condensed lung between the pleural cavity and a dilated bronchial tube: the bronchus and trachea were filled with purulent fluid of the same character as that contained in the pleural cavity. In one instance the patient had been violently salivated before his admission, and a very large portion of the lower jaw had perished in consequence.

Bronchitis.—Bronchitis was the apparent cause of death in three cases. In the first the mucous membrane was universally inflamed, unaccompanied by any condensation of the lung; in the second, in addition to the affection of the mucous membrane, the pleural

cavity contained some effused serum; and in the third case the bronchitis was accompanied by some condensation of aneurism of the aorta, this was situated the lung: the last case was also complicated by the existence of an aneurism immediately in front of the trachea, and by its pressure upon the anterior surface of the tube had diminished its antero-posterior diameter to one half its ordinary size.

Disease of the Heart.—Disease of the heart was apparently the immediate cause of death in five instances: the pericardium was in all these cases affected. In three it was universally adherent; in the fourth case, the lymph effused upon its internal surface had assumed a honey-comb appearance, confining separate small collections of serum between its numerous partitions; and in the remaining case the pericardium contained purulent fluid. A layer of very firm bone had in one instance been developed between the adherent layers of the pericardium. Disease of the mitral valve presented itself in three out of the five cases, and in two of these the aortic valves were also affected: the kidneys were diseased in two and congested in one of the above cases.

Disease of the Brain.—In many cases in which the supposed cause of death was found elsewhere the head was not examined, and therefore cerebral disease may have existed in some cases unobserved. Besides the cases of malignant disease already mentioned, disease of the brain was the cause of death in four instances; in three of these effusion of blood had occurred to a greater or less extent in the substance of the brain, and in one, where erysipelas had preceded death, some effusion of lymph had taken place at the base of the brain, and the corpus callosum, fornix, and septum lucidum, were found softened. The remains of three separate extravasations of blood were found in one of the above cases, consisting of a transparent fluid in one cyst, a yellowish fluid in a second, and a brownish red semifluid substance in a third; in another instance, the cavity containing the effused blood, situated upon the surface of the brain, had become inflamed, and the secretion from its surface mixed with the extravasated blood.

The *spinal chord* was found in one case, for the extent of an inch at its lower part, converted into a pink soft substance. This was accompanied by a soft and spongy condition of the cancellous structure of the corresponding vertebrae, and with inflammation of the kidneys and bladder.

Disease of the Kidneys.—In the great majority of cases disease of the kidneys occasions death by inducing some other disease more immediately fatal. The cases of this nature which occurred have already been enumerated under different heads: five instances, however, occurred in which the kidney was the principal organ diseased, and in which no very evident cause of death was found elsewhere. The brain was examined in two only of these cases, and in both found to contain more fluid than natural, both in its ventricles and in its substance. In all the cases, with one exception, the kidney was reduced in size; upon one occasion one kidney only was present. It was very small and hard, smooth on its surface, with the capsule remarkably adherent, while on the opposite side, the ureter, which was of its natural diameter, terminated above in a cul de sac; around this was some dense vascular cellular tissue, but no appearance whatever of a kidney.* The kidneys were granular upon their surface in all the remaining cases.

A remarkable disease of the bladder accompanied the affection of the kidney in one of these instances. Several large varicose veins were observed in the submucous cellular tissue, near the prostate gland, and in the same situation were several tuberculated elevations, varying in size from a pea to a hazel nut; some of these of the largest size were filled with a white milky fluid; others contained a solid semi-transparent substance, and others again consisted of a yellow opaque matter resembling tubercular deposit. The remaining part of the mucous membrane of the bladder was healthy.

Affections of the Urethra.—Ulceration of the urethra permitting the escape of urine was fatal in three instances. In two of these the opening occurred in the bulbous portions, and in one in the membranous portion of the urethra: the consequent extrava-

sation of urine was situated in the former cases between the perineal fasciæ; in the latter, within the triangular ligament. A fourth case may be allied to these, in which advanced disease of the kidneys accompanied a confirmed stricture. Diffuse cellular inflammation occurred in this case, without any extravasation of urine.

Strangulated Hernia.—Of seventeen patients operated on for strangulated hernia during the year, six died. In one of the cases which proved fatal the patient had been delivered shortly before the operation; in a second the patient was labouring under disease of the brain; and a third was suffering from an attack of fever before the hernia had become strangulated. One of the remaining cases died in consequence of mortification of the bowel, and two proved fatal from inflammation of the intestine and peritoneum. In both these last cases, a sac, formed by the omentum, enveloped the bowel, in addition to the ordinary peritoneal sac. A separate account of these cases will shortly appear, and therefore no farther observations upon them will at present be offered.

Strangulation of the small intestine, unaccompanied by hernia, was in one instance the cause of death. A portion of the small intestine in the form of S had become inflamed, and the different portions glued together by recently effused lymph: a considerable mass was thus formed, the base of which was encircled by another double fold of small intestine likewise retained in its position by recent adhesions. The passage of the bowel was by these means completely obstructed. A diverticulum existed at one portion of the intestine, consisting of a canal about a quarter of an inch in diameter, and four inches long, considerably dilated at its closed extremity, and containing some foreign bodies. This did not appear to be connected with the cause of the obstruction of the intestine.

The following cases proved fatal each in one instance.

Hydatid cysts in the abdomen.—Erysipelas had in this case immediately preceded death. The body was greatly emaciated, but the abdomen enormously distended. The recti muscles were widely separated by the pressure of the abdominal contents, and the parietes consequently rendered so thin, that

* The teeth of this person were all loose, supposed to be the effect of mercury taken before his admission.

some small moveable tumors within the abdomen conveyed the sensation of being subcutaneous. On opening the abdominal cavity, numerous hydatid cysts were seen attached to the omentum: some of these were almost transparent, but in others the parietes had attained considerable thickness. A circumscribed, soft, elevated growth, resembling a warty excrescence, had developed itself from the internal surface of several of these cysts. Almost every part of the abdomen was similarly occupied by hydatids; the contents of the cysts in the neighbourhood of the liver had assumed in several instances a yellow colour, while in contact with the intestine they appeared as though tinged with fecal matter. One very large cyst was situated upon the under surface of the liver, and had become partly imbedded in its substance. Another cyst of very large size was situated above the liver, and by its pressure had made its way through the right side of the diaphragm, encroaching upon the corresponding lung. A smaller one upon the left side had also caused the absorption of the diaphragm and protruded into the cavity of the chest beneath the pericardium. Some small hydatid cysts were also developed from the peritoneum, covering the abdominal muscles.

Hæmatemesis.—The patient in this case died after repeated vomiting of large quantities of blood.

On the upper part of the posterior wall of the stomach the remains of an oval ulcer presented itself. It was perfectly healed, with the exception of one point, where a small rounded mamillary eminence projected from the surface. In the centre of this elevated portion was seen the open mouth of an artery, which proved to be the truncated extremity of the arteria coronaria ventriculi. A large branch was given off immediately before the termination of the artery in the cicatrix of the ulcer.

Effusion of blood on the surface of the spinal chord.—This occurred in a girl 18 years of age, who died suddenly upon the day of her admission into the hospital. The cells of the pia mater for the whole length of the spinal chord were distended with coagula of blood. The extravasation extended upwards upon both sides of the pons varolii, and communicated with a large quantity of

coagulated blood which filled the fourth ventricle. The *iter a tertio ad quartum ventriculū* was also occupied by a narrow coagulum. This was continued into and filled the third ventricle. The lateral ventricles were distended with bloody serum; coagula of blood occupied the floor of each, extending backwards into the posterior horn, and communicating with the effused blood in the third ventricle. One of the vertebral arteries presented near its termination two small apertures, from which the hæmorrhage appeared to have proceeded.

Simple ulcer of the œsophagus.—This patient died in a state of extreme emaciation, having for a considerable time been unable to swallow any solid substance: about an inch above the bifurcation of the trachea an irregular shaped ulcer was found in the œsophagus. The tube was slightly contracted but not diseased above this point; the ulcer was about an inch and a half in length, not surrounded by any particular induration, and extended in one part through all the coats of the œsophagus, but not into the cellular tissue surrounding it.

Imperforate vagina.—The vagina in this case terminated in a cul de sac about an inch and a half from its external opening: from this point the canal was completely obliterated for about half an inch, and above this again became sufficiently distended to contain a pint of fluid. The walls of the vagina in the dilated portion were much thickened, and were lined internally by a uniform layer of greyish-white substance, resembling effused lymph, internal to which was a layer of black matter, apparently a deposit from the black fluid contained in the cavity. This patient died of peritonitis after an operation for the evacuation of the confined fluid.

Erysipelas preceded death in five instances; three of these have already been mentioned under the several heads of compound fracture, disease of the brain, and hydatid cysts in the abdomen. The remaining cases occurred, the one in conjunction with disease of the kidneys, the other accompanied by disease of the liver.

13, Dover Street, Piccadilly,
April 14th, 1844.

REPORT
ON THE
ROYAL MATERNITY CHARITY.

By F. H. RAMSBOTHAM, M.D.

(For the London Medical Gazette.)

DURING the year 1833, there were delivered in the Eastern District of the Royal Maternity Charity, under the superintendence of Dr. F. H. Ramsbotham—

2619 women—Of which cases

22 were twins—one in about every 119 cases: of these in 6 cases both heads presented; in 15 the presentations were head and breech, or inferior extremities; and in 1 both were breech, or inferior extremities. In 9 of these cases both children were boys; in 6, both were girls; and in 7 they were of different sexes.

1372 children were males.

1269 children were females.

2437 were presentations of some part of the head; of these 12 were face presentations—about 1 in every 220 births.

64 were presentations of the breech, or some part of the lower extremities—about 1 in every 41½ births; of these 17 were twins.

4 were transverse presentations—about 1 in every 660 births; 1 of these cases was between 7 and 8 months. All the children were delivered by *turning*; the premature child living, the others still-born. In one case the membranes had given way 63 hours before I saw the patient.

In 2 the placenta was implanted over the os uteri; one was a breech presentation: the child was extracted alive; the woman did well. In the other case the child was *turned*; it was born dead, and the woman died from the effects of the previous flooding, three hours after.

5 were complicated with alarming accidental hæmorrhage before delivery, not the result of placental presentation—about 1 in every 524 cases. In all these cases the flooding ceased soon after the membranes were broken; all the children were expelled living, and all the women did well.

In 18 cases the placenta was retained within the uterus, either by irregular contraction, or atony of the uterine fibres, or by morbid adhesion

between the uterine and placental surfaces, requiring the introduction of the hand for its extraction—one in every 145½ cases. 2 of these were twin cases; another was at 6 months. One woman died of the effects of hæmorrhage fifteen minutes after its removal; another in two hours, from the same cause.

Another of these patients died of pneumonia fourteen days after delivery. She went on very well till the 8th day, when she was moved into another house; she was immediately seized with shivering, pneumonia supervened, and she died in six days. It was in January.

9 were complicated with alarming hæmorrhage after the natural expulsion of the placenta—one in every 291 cases. One was a lingering labour; two were twins; in one of these there was some hæmorrhage between the births, as well as after. One woman died in two hours after the placenta had passed.

3 were delivered by craniotomy—one in every 873 cases; one was the woman's seventh child; her labours had always been lingering, in consequence of a deformity at the pelvic brim; she was allowed to go on as long as was consistent with her immediate safety, and, after the long forceps had been tried in vain, the head was perforated. Another was the woman's eighth child; she also possessed a narrow pelvis; the forceps were applied without success: the woman died on the 8th day from diffused pelvic inflammation. The child was much larger than ordinary. This patient might, perhaps, have been saved, if she had been delivered sooner; but I was most anxious to avoid perforating the head, as she had had so many living children, and I waited therefore longer than was safe, as the result proved. The other was the woman's third child; it was hydrocephalic.

In 3 premature labour was induced—one in every 873 cases; in two of these cases the operation of puncturing the membranes was performed; one of the children was born living; the other still, the feet presenting; one was brought on by the ergot, the child was living. In all the necessity of having recourse to this measure originated in deformity of the pelvis.

5 were complicated with puerperal convulsions—about one in every 524

cases: in 3 the attack commenced before the birth of the child; 1 while the head was on the perineum, the child was born living; 1 at 7½ months of pregnancy, the labour came on in 12 days, the child was dead. The other, the day before labour, the child was living; she had suffered one convulsion at a month previously. In one case the fits came on in 5 hours, and in the other 7 days after labour. All these women were bled and purged with great relief; and, except the last, who died on the fourteenth day, they recovered.

16 women died either from puerperal causes, or within the puerperal month—one in about every 166½ cases; only 9, however, of these as a consequence of labour, being 1 in about every 291 cases, for 5 died from chronic pulmonary disease, one from chronic laryngitis, and one from typhus fever, caught during pregnancy.

2536 children were born living; 85 were born still—about 1 in every 31 births.

Of the Deaths,

1 occurred three hours after delivery, under a placental presentation from hæmorrhage.

2 from hæmorrhage, after the removal of an adherent placenta: one in 15 minutes; the other in two hours.

1 from hæmorrhage two hours after the natural expulsion of the placenta.

1 on the 14th day after delivery, from the effects of puerperal convulsions.

2 from fever—one in four hours after delivery, the woman being in the last stage of typhus when she went into labour; the other from common continued fever, in the third week after delivery.

1 from diffused pelvic inflammation 9 days after delivery by craniotomy.

2 from pneumonia—one on the 14th day after delivery, which was complicated with adherent placenta; she was most injudiciously carried to another house on the 8th day, as stated above: the other in the fourth week.

5 from confirmed phthisis—one in five hours after labour; one in 5 days; one on the 11th day—she had suffered severely from hæmoptysis during the whole of her pregnancy; one in a fortnight; and the other in the 4th week.

1 from chronic laryngitis a few days after delivery.

Of the Still-born children,

22 were premature—in one case labour was induced artificially.

16 were putrid, at full time, or nearly so.

11 were presentations of the breech, or inferior extremities, at full time, or nearly so.

4 were transverse presentations, at full time, or nearly so.

With 7 the funis prolapsed by the side of the head; the funis prolapsed also in two other cases, but the children were born living, naturally.

1 was under a placental presentation.

3 were delivered by craniotomy; one of these children was hydrocephalic.

2 were monstrous; one of these acephalous.

2 were hydrocephalic, expelled entire.

3 were under lingering labour.

1 was after an attack of convulsions, premature.

With 1 the mother was dying from typhus, premature.

11 were at full time, or nearly so, head presenting, not putrid, nor delivered by art.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

Homœopathy Unmasked: being an Exposure of its principal Absurdities and Contradictions; with an Estimate of its Recorded Cures. By ALEXANDER WOOD, M.D. Edinburgh, 1844.

THIS work, able and searching as it is, comes rather too late; for the mask of homœopathy, like that of my aunt Dinah, is worn so thread-bare, that it can easily be seen through, and scarcely requires to be raised. But as some persons in the remote district of Wastdale, in Cumberland, continued to pray for Queen Anne thirty years after her decease, so it may happen that a few persons, far removed from the current of public opinion, may pertinaciously retain a belief in homœopathy, and we therefore strongly recommend to their perusal this volume.

Dr. Wood has acquitted himself in a masterly way, and wrestles with the homœopaths, especially those of Edinburgh, like a giant. He has them

fairly on the hip, and ere he lets them out of his powerful grasp, they suffer so severely, that they must halt for it is as long as they live. But we have long foreseen that hydropathy would prove the true euthanasia of homœopathy, and we turn therefore to a manual of the more recent delusion, entitled—

The Hand Book of Hydropathy; for Professional and Domestic Use: with an Appendix on the best mode of forming Hydropathic Establishments, being the result of twelve years' experience at Graefenberg and Freywaldan. By Dr. J. WEISS, formerly Director of the Establishment at Freywaldan, latterly of Stanstead-bury House, Hertfordshire.

Most oracular sentences have a two-fold meaning on application. This is clearly the case with the dogma of the Grecian philosopher, who asserted *omnia ex aqua*, by which he intended to signify that not only all mundane things originated from water, but that this element was to be the great renovator of all things. The present age has demonstrated this—to the great satisfaction of “the dabblers in cold water.” It frequently occurs that a superior genius rises to keep alive valuable truths, and instead of attempting, as some have done lately, to rob Priessnitz of his claim to the discovery of the universal curative properties of water, and transfer the merit to the illiterate peasantry about Willowbridge, in Staffordshire;* we claim this for the illustrious Dean Swift, whose eulogy on a fashionable watering place is the very essence of hydropathy:—

All you that would refine your blood,
As pure as famed Lewelling,
By water clear, come every year
And drink at Bellaspelling.
Although disease your skin enrich
With rubies past the telling,
'Twill clear your skin, ere you have been
A month at Bellaspelling.

* “In Staffordshire, at Willowbridge, they have a more bold practice than either the Greeks or the Romans used; they go into the water in their shirts, and when they come out, they dress themselves in their wet linen, which they wear all day, and much commend that for closing the pores, and keeping themselves cool; and that they do not commonly receive any injury, or catch any cold thereby, I am fully convinced from the experiments I have made of it.”—Sir John Floyer's History of Cold Bathing, in the Dedication.

Tho' ladies' cheeks be green as leeks,
When they come from their dwelling,
The kindling rose within them blows
While she's at Bellaspelling.
The sooty brown, just come from town,
Grows here as fresh as Helen;
Then back she goes to kill the beaux,
By dint of Bellaspelling.

The pained in mind, the puff'd with wind,
They all come here pell mell in,
And they are sure to find a cure
By drinking Bellaspelling.
Tho' dropsy fill you to the gills,
From chin to toe high swelling,
Pour in, pour out, you need not doubt
A cure at Bellaspelling.

We therefore entirely agree with Dr. (?) Weiss, that “hydropathy is by no means an invention of modern times.” The attempt to employ water as a cure for all diseases was made in this country above a hundred years ago, by Sir John Floyer (see his History of Cold Bathing, London, 1732,) and failed, though, like the work of Dr. Weiss, every page abounded with a “modern instance.” For amusement we infinitely prefer old Sir John's book, and for honesty of purpose we exalt it far above the modern one. How unpalatable to the present race of hydropathic practitioners must the following sentence be: “Men ought to be very just in what they publish and assert, in that tender and nice concern of *life*; for all things in reference thereunto ought to be considered well, and treated with the greatest *caution*; for there lies no *writ of error* in the *grave*, but the sick man is finally concluded by the knowledge or ignorance of his physician. But where knavery and neglect help to compound the *doctor*, there, I say, the patient is in a deplorable condition, more from his director than his disease,” p. 186. “Here the patient is in a pretty pickle, being pretty sure to be doused according to the depth of his own purse, or his doctor's conscience; and this I call both a *felony* and *murder*, for the man is first robbed, and then *killed*,” p. 202. That these hard terms are not misapplied, let Dr. Weiss himself bear witness. “It happens, unfortunately, but too frequently, that patients are, without further consideration, wrapped in wet sheets in rapid succession, and subjected to ablutions or baths, without any regard to the temperature of the body or to the development of the eruption. I have

even seen patients left in the wet sheets day and night, where dropsy had already appeared; where the natural warmth of the body was reduced by this officious interference. I have further seen these patients troubled by one application of cold water after the other, till none was left untried. Is it, then, to be wondered at, that patients should sink under this ill treatment?" p. 178. The plain and obvious answer of common sense is, "Not at all." Yet, as old Floyer again hath it, "Such is the force of one knave on a crowd of fools," p. 198. Dr. Weiss assigns as a reason for adding one more to the numerous treatises on hydropathy, that "the majority of them are absolutely injurious, and wholly objectionable, inasmuch as they diffuse false notions of the nature of this system of treatment, and recommend water without limitation in every disease. Many books, by gross representations of cures of important diseases in an incredibly short space of time, must of necessity prove more hurtful to the cause of hydropathy, than farther the propagation of a discovery of so much benefit to mankind." Preface, p. 4. In other words, the authors of these books, and the followers of the system are—quacks. How does Dr. Weiss propose to distinguish himself from them? By insinuating that he is somewhat superior to Priessnitz himself, as attested by cases published in the German newspapers. In this country these are the very marks of the beast. In the true spirit of quackery, he attributes all the diseases of modern times to men forsaking the use of water; and maintains that a remedy is to be found in a return to the use of it.

Before attempting to give a reason for anything, it is well to ascertain whether it be a fact or not. Now, nothing can be more unfounded than the statement that the race of mankind has degenerated. Civilized man is much stronger than man living in a state of savage nature. This is no vague assertion, but an established fact. "In order to procure some exact comparative results on this point, Peron took with him, on his voyage, an instrument called a dynamometer, so contrived as to indicate, on a dial-plate, the relative force of individuals submitted to experiment. He directed his attention to the strength of the arms and the loins,

making trial with several individuals of each kind; viz. twelve natives of Van Diemen's Land, seventeen of New Holland, fifty-six of the island of Timor, seventeen Frenchmen belonging to the expedition, and fourteen Englishmen in the colony of New South Wales. The following numbers express the mean result in each case; but the details are all given in a tabular form in the original.*

	STRENGTH.	
	In the arms.	Of the loins.
1. Van Diemen's Land	50·6	· · ·
2. New Holland	50·8	· · · 10·2
3. Timor	58·7	· · · 11·6
4. French	69·2	· · · 15·2
5. English	71·4	· · · 16·3

These results offer the best answer to the declamations on the degeneracy of civilized man.

Further, out of 100 individuals born at the same time in the savage state, and 100 in the civilized, a much larger number will be found alive at the age of 60 of the latter than of the former. The reason why all savages are strong (though not so strong as well-fed Englishmen) is, that none but the strong survive and reach maturity, the feeble all, without exception, perishing in infancy, as has been ably pointed out in Dr. W. C. Taylor's Natural History of Civilized Society.

Mankind have not degenerated either in strength or longevity in consequence of the usages of civilized society; any argument, therefore, in favour of water, on the assumption of the contrary, must prove—unstable as water.

That some have derived much benefit from a journey to Gräfenberg, and relaxation from excessive occupation, or a career of fashion, joined to plain fare, exercise, and good ablution, we are far from denying. The utility of these *juvantia* Dr. Weiss clearly admits, in his instructions for the "forming of Hydropathic Establishments:" "The amusements and recreations which may be permitted to patients are—concerts, music in general, short dances, various games, gymnastic exercise in the open air, by which the various muscles of the body are brought into play; and, in addition to these entertainments, cheerful, amusing, light reading."—

* Peron, Voyages, t. I. chap. xx. p. 416; t. 2, p. 460.

p. 438. But here he has been again anticipated by Dean Swift.

Good cheer, good air, much joy, no care,
Your sight, your taste, and smelling,
Your ears, your touch transported much,
Each day at Bellaspelling.

Here all you see, both he and she,
No lady keeps her cell in,
But all partake the mirth we make,
Who live at Bellaspelling!

We do not wish to argue against the use of any thing from its abuse. On the contrary, we rejoice greatly at the erection of baths for the working-classes in Liverpool and Edinburgh, and hope to see so laudable an example followed by every town in the kingdom. But let the managers of these beware of putting them or themselves under the direction of a professed hydropathist.

Hic niger est, hunc, tu, Romane, caveto.

Here we had hoped to rest from our labours; but this roguery will be the death of us! We had got so far when we had laid on our table,—

The Practice of the Water Cure, with authenticated Evidence of its Efficacy and Safety. Part 1, containing 70 authenticated cases, the opinions of English medical practitioners, &c. &c. By JAMES WILSON, M.D. &c. &c.

HERE we have the cloven foot undisguised, not only in matter, but in manner and in form: flimsy paper, double columns, minion type, and six sheets and a half, all for the sum of one and sixpence! Dear by comparison at the money, nevertheless; for we have Hannay and Dietrichsen's Almanac, a goodly octavo volume of advertisements of quack medicines, with letters *authenticating* their efficacy, for sixpence! And if there be here the ample space taken up by the titles of the patent medicines and the letters bearing witness to their virtues, there is at least the almanac, with the days of the week, and month, and year; the rising and setting of the sun, moon, and stars; the eclipses and occultations of these luminaries; the holidays; the proper lessons for Sundays and festivals; &c. &c.; all of which, we should say, was well worth the money—sixpence. The book would be dear, indeed, at a penny, were there not the almanac. What, then, shall we say in regard to the price of a kindred volume—without any almanac? What, but that it is excessively dear? and so, in truth, we hold it.

In the account of Dr. (?) Weiss, we took the light tone, and made Dean Swift play the part of critic; we were inclined to treat Dr. James Wilson more seriously; he is, we believe, one of ourselves—a man regularly educated to the profession of medicine; but in truth we want the heart—the joke dies away in our pen; a flood of regret comes over our heart with the thoughts of the fallen angel that possess our mind,—and so we end.

MEDICAL GAZETTE.

Friday, May 10, 1844.

"Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri; potestas modo veniendi in
publicum sit, dicendi periculum non recuso."

CICERO.

APOLOGY AND PLEA

OF THE

COMPANY OF APOTHECARIES.

It has transpired somehow or other, and before the "Bill is on the table of the House," that the minister's intended measure for the regulation of the medical profession contemplates the suppression of the Apothecaries' Company as a body having authority or control over the education and license of the future practitioner.

The Worshipful Company of course do not like this; and how should they? how rare the instances of voluntary retirement into privacy and obscurity, among those who have once enjoyed the sweets of power! They cannot make up their minds to be extinguished, they do not like to be spoken of in the past tense—*fuimus* Troës!—and they have just sent forth "A Statement on the subject of their administration of the Apothecaries' Act, with reference to some supposed features of Sir James Graham's promised measure of Medical Reform."

The document is a sort of apology for their past conduct; it is further a claim set up for an exertion of influence of the most beneficial kind upon the progress and present state of

the medical profession, and it includes by implication a plea for the propriety of continuing them in their authority.

To listen to the Worshipful Company through the pen of their advocate, one would fancy that they had been in advance of medical science, leading the way in the race of inquiry, and enriching every department of the profession by new views, new facts, new applications of former knowledge. These worthy gentlemen, however, mistake effects for causes, and dragged along with the chariot at its tail, they think they have been in advance of it, and instrumental in bearing it forward. To take the word of these respectable gentlemen, one would fancy that the world of medical science had gone to sleep with the solitary exception of themselves, and that all that has been done of late years—say in the course of the last thirty years—since the eventful year 1815, had been done in virtue of their interference. That the Laennecs, the Bayles, the Broussais, the Andrals, the Louis, and Richard Brights, the Prouts, the Davys, Daltons, Liebig's, and Dumas, the Robert Lees, and Naegles, the Schwanns, the Müllers, Valentins, Bischoffs, Wharton Jones's, Rudolph Wagners, Bowmans, and Goodsirs, and a host besides, too long a list to name, of those who have added new strings to Apollo's lyre, had all been men of their engendering: had all become what they are, or were, in virtue of the "Act for Regulating the Practice of Apothecaries, throughout England and Wales"—God save the mark! and Jove, in his next commodity of modesty, send some—a cargo at least—by the way of Bridge Street, Blackfriars!

It would have been strange indeed, that, whilst all the world were in motion, any particular set of men, even the men in the aforementioned locality,

should have stood altogether still. Whether as individuals or as bodies, it is notorious that we have little influence on the current of events; our business both as individuals and as members of corporate bodies—as a minister of the Crown once most wisely said, in his place in Parliament—is rather to adopt such measures as the common consent and general voice of the community seem to require, than to originate new ones. If the education of the medical profession have improved since 1815, as who will say that it has not? the Apothecaries' Company have very certainly had nothing to do with the improvement: our thanks may indeed be due to them that they adopted the advancement which, by common consent, was required; but they had no more influence in creating the taste or the necessity for that advance than they had in the recent discovery of Victoria-Land at the South Pole. Or is the improvement that has gone on in Scotland, in France, in Germany, and America, during the last thirty years, in the general and particular education of the physician and surgeon, a reflex of the dazzling lustre shed over the world by the Examiners of the Worshipful Company of Apothecaries in general court assembled? We rather opine that it is not; it is the progress of knowledge that has made a greater amount of knowledge necessary; no enactment of Apothecaries', or any other company.

That this body of men—it may be said the only body having an available legal authority, 1st, to secure the public in the possession of competent medical advisers, and 2d, to defend them from the inroads of the ignorant empiric, have done all that they might have done—all that ought to have been attempted, at least—we deny. They have made good enactments—we should rather say, have *adopted* good enactments—with regard to the education

of the candidates for their license; for they have taken the curriculum of the University of Edinburgh for their model, and just abated so much from its completeness as their different circumstances seemed to make needful; but we think that we have shewn, in our number for the 19th ultimo, that they have proved themselves utterly incompetent to secure the fulfilment of their own regulations. They have made the degrading system of grinding imperative upon all who present themselves for examination before them; without it, the most diligent student, the medalist of two, three, or four classes, has no security that he will pass; and as a set off to this they suffer themselves to be grossly deceived by many of the young men who come before them. If science could be rendered ridiculous, it would be so by the pretensions to intimacy with her set up by some of the examiners at Apothecaries' Hall, and the questions got out of colloquia medicas and vade mecums, which they propound upon light and electricity, optics, mechanics, pneumatics, and the primum mobile, to the Candidates.

And then, what signifies publishing, as they do in this "Statement," the number of those who have passed, and of those who were rejected? For what term was the rejection? Of the number rejected, how many were found incompetent in the end? To the first query we supply the answer—for a few months at farthest; sufficient time to enable the youth to get better crammed before his next ordeal, never enough to enable him to add one iota, through his own diligence, his own sustained efforts as a true student, to his stock of solid professional information. In six months he comes up again; and he is either passed or rejected: passed, he is no whit better than he was before; rejected, he returns to the

trough he had but just quitted; by and by he presents himself for the third time, and then, and as a matter of course, he passes.

The Apothecaries' Company, again, it is notorious, have not done all they ought to defend the public from the malpractices of empiricism. If their prosecutions have sometimes, nay generally—for we would not willingly make matters worse than they are—been directed against uneducated and ignorant practitioners, they have sometimes also been instituted against men of liberal education, men having a diploma from the College of Surgeons or an University, and of perfect respectability in life and conduct.

But the existence of any Company of Apothecaries, as practitioners of medicine, in the present day, is an anomaly, which, like other anomalies connected with wont and usage, remains in England after it has disappeared from the face of the earth everywhere else. There is no such person as an apothecary, in the sense in which we must interpret him according to the Apothecaries' Act of 1815, even so close at hand as Scotland, nor in France, nor Germany, nor, we believe, America. An apothecary is a shopkeeper, a dealer in herbs and simples, drugs and unguents. Take the poet's definition of the man:—

"I do remember an *Apothecary*—
And herabouts he dwells—whom late I noted,
In tattered weeds, with overwhelming brows,
Culling of simples:—meagre were his looks;
Sharp misery had worn him to the bones;—
And in his needy shop a tortoise hung,
An alligator stuffed, and other skins
Of ill-shaped fishes; and about his shelves
A beggarly account of empty boxes,
Green earthen pots, bladders, and musty stores,
Remnants of packthread and old cakes
Of roses were thinly scattered to make up a show.
Noting this penury, to myself I said:
An if a man did need a poison now,
Whose sale is present death in Mantua,
Here lives a catiff wretch would sell it him."

The medical profession consists of physicians and surgeons, with either of whom the obstetrician associates himself, and there is the druggist's, the

apothecary's shop, from whence the needful medicines can be procured. The *apothecary* to the army and navy is the tradesman who supplies these establishments with the simples, chemicals, and galenicals, which their medical officers require,—Apothecaries' Company have but just obtained a large slice in the very profitable traffic of supplying drugs to the army. Dealers in medicines, therefore—very necessary men, we will grant them—we will never allow that the apothecary, as the Worshipful Company meets us in the mercantile world, is any part or parcel of the *medical profession*. We hold the conjunction between the practice of medicine and the trading Company, effected in 1815, as one of the most unfortunate incidents that ever befel the profession of physic, and we do say emphatically that we rejoice most heartily in the prospect of a speedy separation between them—*sit perpetua*! is our prayer. The alliance has done much to degrade us in the public estimation; the idea of the petty trader kept constantly before the mind of the

world, the idea of the professional man has been too much obscured, or even totally lost sight of. The fellows and members of the Royal College of Surgeons of Edinburgh, never necessarily associated with the apothecary, repudiated his alliance of themselves some time ago; the profession in the Scottish metropolis consists of physicians, of surgeons, and of physician-surgeons—men who, like the medical officers of the army and navy, do not confine themselves strictly to one branch of the profession, but practise either indifferently, have the same education, and are of the same grade as those who do. The prescriptions of all these gentlemen go alike to the chemist and druggist's, to the apothecary's shop, to be prepared. This it strikes us is the point to which all the efforts of those who desire to uphold the honour and to increase the influence and usefulness of the medical profession ought to tend; the paramount object to be kept in view—a divorce between everything like traffic in medicines and the exercise of the healing art.

TREATMENT OF MEDICAL MEN BY BOARDS OF GUARDIANS.

To the Editor of the Medical Gazette.

SIR,

CONSTANTLY reading your valuable periodical, and consequently judging your feelings upon these points, I trust I am not acting intrusively in forwarding for insertion the following account, shewing the manner in which

professional men are *generally* treated by the Board of Guardians of the Poor in the Isle of Wight; and I shall be also further and very importantly obliged by the expression of your opinion (as also that of some of your able correspondents) as to the absolute justness or unjustness of the following items; and consequently the fairness, or otherwise, of the conduct of the Board in offering such a remuneration as is shewn by the subjoined order.

“Godshill, Isle of Wight.

“The Board of Guardians,
House of Industry, Isle of Wight.

“To J. J. E. Porter, Surgeon, &c.

“To medicine and attendance on the wife of Isaac Wadmore, labourer to Osmond Johnson, Esq. of Wroxall (as follows):—

		£	s.	d.
“1843.				
“Dec. 16th.—To night journey,	£1. 1s.; two draughts, 3s.		1	4 0
19th.—To night journey,	£1. 1s.; one draught, 1s. 6d.		1	2 6
	Bleeding, 2s. 6d.; mixture, $\frac{1}{2}$ pint, 2s. 6d.		0	5 0
20th.—Journey, 2 $\frac{1}{2}$ miles, 3s. 6d.; mixture, 2s. 6d.; draught, 1s. 6d. (laxative)		0	7	6
22d.—Journey, 3s. 6d.		0	3	6

£3 2 6

As will be seen by the extract from the order of the Board, a mistake was made, this case being described as a labour.

"To surgical attendance on Mrs. Williams, widow, of Wroxall, Isle of Wight (as follows); as also on Benjamin Cheverton, labourer, Rond :—

		£	s.	d.	
"1844.					
"March 10th.—To stopping long continued and dangerous bleeding from the nose, for Mrs. Williams, widow, of Wroxall, £1. 1s.; journey, 3s. 6d.; medicines, 4s. 6d.		1	9	0	
12th.—To reducing dislocation of the ankle-joint, and fractured leg (the inner malleolus), for Benjamin Cheverton, labourer to Francis Fleming, Esq. of Rond, £2. 2s.; journey, 1½ miles, 2s. 6d.; draught, 1s. 6d.; quart bottle lotion, 5s.		2	11	0	
13th.—Journey, 2s. 6d.		0	2	6	
			4	2	6
Wadmore's Account		3	2	6	
		£7	5	0	

In Wadmore's case the district surgeon had been in attendance nearly, or may be more than, ten days prior to my being first called. The woman was labouring under violent spasms, I think, probably dependent upon the passage of a biliary calculus, though this opinion has been much objected to. However, "*finis coronat opus*," she recovered under my care.

In Mrs. Williams' case the district surgeon was *first* applied to, and sent some plugs of lint steeped in Tinct. Ferri Hydrochlor., desiring that they should be put up her nose; but that, if the bleeding did not cease, they were to come to him again (a distance of upwards of eight miles, viz. from Wroxall to Newport). The bleeding continuing, I (living little more than two miles off) was sent for, and most readily and immediately went, when, by continuing for upwards of four hours to employ the method suggested by Dr. Negrier, Angers (vide MED. GAZ. vol. i. 1842-3, fol. 429), which I have in many cases very successfully adopted, without, as yet, a failure, I had the satisfaction of perfectly arresting the alarming hæmorrhage.

Query.—In these two cases, were not the poor people justified in sending for me? and was I, being the nearest surgeon, not fully justified in attending, and sending my accounts (as has always been customary) to the Board?

In the third instance (that of Benjamin Cheverton), I imagine that the general medical order of the Poor Law Commissioners, dated March 12th, 1842, or rather the following quotation therefrom, may, or ought to be, considered the law bearing upon the case :—

"6. Treatment of simple fractures, or simple dislocations, of the thigh or leg, £3."

Consequently, not being in possession, at that time, of the general medical order, I have not charged enough by 9s.

The following order was forwarded to me from the Board :—

Extract.—"Ordered that the Sum of Three Guineas be paid to Mr. Porter, of Godshill, Surgeon, for his attendance on the Wife of Mr. Isaac Wadmore, *in labour*; on Mrs. Williams, with a bleeding at her nose; and on Benjamin Cheverton, whose ankle was dislocated by the foundering of a gravel pit."

Upon my remonstrating with Mr. Hearn, Solicitor, Clerk to the Board, the reply was, "You may bring your action, sir. Having surgeons of our own, the Guardians are not obliged to pay you a single farthing."

You will now, Mr. Editor, be conferring a personal obligation upon me by replying to the question—Have I acted unjustly, and consequently, unprofessionally, towards the Board of Guardians by exorbitant and illegal charges? or have they dealt unfairly by me, in taxing my accounts to the extent they have done? I think it right to add, that a short time since, being called to the assistance of a midwife at a difficult labour, I, as has always been customary, sent in my account (£1. 1s.) to the Board, this fee having been invariably allowed: they were however pleased to insult me, by sending a cheque for 10s. 6d. *specified as for difficult midwifery!!* which I returned, telling them that I had too much respect for the profession of which I have the honour to be a

member to think of so far disgracing it as to receive such a fee.

I much fear I am extending this to too great a length, but hope the importance of the affair, not only to me but to the profession generally, will plead my excuse.

I have the honour to be, sir,

With respect, yours,

J. J. E. PORTER, Surgeon.

Godshill, Isle of Wight.

May 1st, 1844.

[We feel persuaded that no professional man can hesitate for one moment in concluding that Mr. Porter has been most unhandsomely and unjustly treated by the Board of Guardians. The sum they sent him is less than that which he was entitled to have charged for treating either of the injuries sustained by the man Cheverton alone. If £3. 3s. be allowed for dealing with a simple fracture or dislocation, certainly the skill required to treat successfully a case in which there is both a fracture and a dislocation is not diminished, but on the contrary, greatly increased; and a good advocate would find no difficulty, from the testimony of the first men in the profession, of satisfying a jury that if £3. 3s. be the fair remuneration in the simple case, £6. 6s. is not a shilling too much in the compound one. Dislocation of the ankle, complicated with fracture of the inner malleolus, is one of the serious injuries; and if Cheverton recovers, and is able to maintain himself, the Board of Guardians have to thank Mr. Porter that they have not a helpless man, with perhaps a large family, to maintain for the rest of his days. The other items in Mr. Porter's account are perfectly fair; they are extremely moderate. Mrs. Williams would probably have lost her life from hæmorrhage, but for his interference, and there might have been another family to support there; and who shall say, that a journey of 24 miles in the night season, in the month of December, is highly charged at the rate of a guinea? In the day time the same distance is charged at 3s. 6d.! And then, see the amount of attention bestowed upon the respectable medical practitioner by the Board of Guardians, or their instrument Mr. Hearn, Solicitor. His anxious attendance on the poor woman, undoubtedly labouring under severe illness, inasmuch as he was twice sent for in the

night, is carelessly set down to the score of difficult midwifery—and we all know how much is involved in the name—long hours of painful attention, the life of a fellow creature on our hands all the while, and that life only saved at last by the skill of the practitioner! How much do the liberal Guardians through their Clerk, Mr. Hearn, allow? the magnificent sum of ten shillings and sixpence! Surely the medical man has a strong claim to protection against such petty tyranny, such scurvy treatment. To bid him bring his action at law is a mockery, in the indefinite state and ever varying interpretation of our common code. There ought to be a central Board composed in part of medical gentlemen—a physician and a surgeon, a barrister and a layman—to decide on such cases as this of Mr. Porter.—ED. GAZ.]

POLYPUS OF THE LARYNX: LARYNGOTOMY; CURE.

By M. EHLMANN,

Professor of Anatomy to the Medical Faculty of Strasburg.*

THE nature of the disease under which the patient, a woman thirty years of age, was suffering, had been accurately diagnosed by Dr. Schmitt: a fibro-cellular excrescence engaged in the rima glottidis had reduced the patient to extremity; suffocation was imminent, and nothing but prompt measures could give her a chance for life. The first and most necessary step was to facilitate respiration: for this purpose tracheotomy was performed, and a canula being introduced, the patient breathed with perfect freedom. "Two days afterwards I carried out my purpose," says M. Ehrmann, "and happily succeeded in seizing with the forceps, and shaving off with my knife, a polypous excrescence, which grew from the whole length of the inferior ligament of the left side: the growth was brought clearly into view by the separation of the thyroid cartilage cleft in its middle. On the sixth day the patient was doing perfectly well.

TWINS; FOOTLING PRESENTATION;

WEDGING OF THE TWO HEADS, NECK AND HEAD TOGETHER, IN THE PELVIS; ARTIFICIAL DELIVERY, WITH LOSS OF FIRST CHILD; RECOVERY OF MOTHER, AND SAFETY OF SECOND CHILD.

AT seven in the morning the membranes had given way, and the feet of a foetus almost

* Comptes Rendus, 1 Avril, 1844.

immediately followed the gush of liquor amnii. The midwife in attendance proceeded at once to disengage the child; but before she could get it away a very violent pain occurred, with unusual suffering referred to the cavity of the pelvis. The infant, born all save the head, could not be brought farther, and the pains only recurring at intervals of a quarter of an hour soon died away entirely. Assistance was sought at twelve, and again at three o'clock in the day. The body of the half-born foetus was cold, darkly livid, without pulsation, and had evidently been lifeless for many hours. Every attempt to get it away proved vain; it was in fact now ascertained that with the head belonging to the foetus that was partially born, there was the head of a second foetus interlocking, which rendered every prospect of effecting the delivery nugatory. The strength of the mother began to fail, and there was nothing for it but to proceed to the apparently barbarous but indispensable process of severing the body from the head of the dead foetus. This was done, and the head was then readily pushed back into the cavity of the uterus. No pains supervening, the forceps were applied, and the second infant was brought into the world alive. But now profuse hæmorrhage set in, which was only controlled by injections of pure brandy. The grand object was now to extract the head, in which great difficulty was experienced; at length, however, it was caught between the blades of the forceps, and being brought down within reach of the finger, this was got into the mouth, and the delivery accomplished. The placenta soon followed. The mother and second child did well.—*Dr. Hoffmann, in Casper's Wochenschrift*, No. 11, 1844.

SCROFULOUS ABSCESS OF THE NECK,

WITH PERFORATION OF THE JUGULAR VEIN: DEATH.

A CHILD, five years of age, on recovering from scarlatina, suffered an attack of inflammation and swelling in a cluster of subcutaneous glands situated on the right side of the neck. The glands suppurated. Fluctuation became distinct. A certain tremor, which was perceptible by the hand, and noise which could be heard by the ear applied to the abscess, were held suspicious symptoms, and much hesitation was therefore felt in puncturing the tumor; in fact, this was not done until after a consultation held with a regimental surgeon, who approved of the measure. The abscess was punctured, but immediately an ample stream of blood revealed the true nature of the mischief. The blood at first had a dirty red colour, undoubtedly from the admixture of pus; but before it could be arrested it appeared

quite pure. The puncture was forthwith closed, and gentle pressure maintained by means of a bandage; but this was scarcely secured when the patient expired.

On an examination after death it was found that the external jugular vein was perforated like a sieve in a space three quarters of an inch in length, and that the parts of the vessel above and below this portion were discoloured and soft.

The abscess, which was regarded as metastatic in its nature, had, in fact, extended to the walls of the vein which lay over it, and perforated them.—*Dr. Hoffmann, in Casper's Wochenschrift*, March 30th, 1844.

[Our readers, on perusing the above interesting case, will all remember one almost precisely similar to it which occurred in the practice of a distinguished metropolitan hospital surgeon, some two years ago. The sole difference between the two cases was, that whilst in *Dr. Hoffmann's* the vein was perforated, in the one alluded to it was the artery that was ulcerated.—*ED. MED. GAZ.*]

ON THE TREATMENT OF ARTICULAR RHEUMATISM

BY TINCTURE OF COLCHICUM, NITRE, AND BLOODLETTING.

DR. E. MONNERET (*Archives generales de Médecine*, Mars 1844) has made some interesting observations on these points of practice, which deserve the serious consideration of the profession. Having shown in a preceding paper (*op. cit.* Jan. et Fev. 1844) that the sulphate of quinine had no title to rank as a therapeutical agent in rheumatism of efficacy superior to many others, he now proceeds to test the value of the articles indicated above.

Twenty-five patients were treated by the tincture of the colchicum root, 8 by nitre, and 19 by copious blood-letting.

The energy of the preparation of colchicum was first ascertained—it was very powerful. The greater number of the patients took from 4 to 16 grammes (one dram to four drams) in the course of the 24 hours, in one, two, or four divided doses. No smaller dose than a dram was ever administered, and several of the patients took it for 7, some for 10, and others for 13 days. The medicine was not discontinued in any case until it was ascertained to have no effect upon the disease.

In 8 of the patients, the diminution, or even total disappearance of the symptoms of rheumatism, coincided with the exhibition of the tincture of colchicum. The rheumatism in these cases was either of some days' duration, and was scarcely accompanied with febrile symptoms, and then ended in 12 or 14 days, or it was completely

chronic. In either case the powerful revulsion produced by the T. Colch. on the bowels sufficed to suspend or to expel the disease: the improvement always coincided with the diarrhoea. In no case did the T. Col. produce amendment or cure of rheumatism by any of those specific and occult properties which have been recognized in it by certain writers. In a few rare cases where its action was beneficial and rapid, it operated as a true drastic purgative. With regard to any complications which existed with the disease on the side of the heart, M. Monneret observes that it is scarcely needful for him to say that they were in no wise modified by the tincture of colchicum. If the effects of this medicine upon rheumatism, then, are nil in fact, which seems quite certain, it is much otherwise in so far as the abdominal viscera are concerned. Upon this point considerable difference of opinion appears to prevail: some say the colchicum occasions no intestinal disturbance, and that it does not purge; others maintain that it abates the pulse in force and frequency; and almost all unite in lauding its effects in rheumatism, &c. I have watched its influence in a sufficient number of instances, says M. Monneret, to have no hesitation in stating exactly what I have seen. In 25 patients to whom the tincture of colchicum was administered, I observed but a single order of phenomena at all referrible to the gastro-intestinal system. The most remarkable among them were nausea and vomiting, diarrhoea, colic pains, and borborygmi, and the whole of these effects almost immediately followed the exhibition of the medicine in large doses, and for a certain time. In other instances diarrhoea was the prevailing feature—there was little sickness or vomiting, but the alvine evacuations were copious and repeated. In a third and very small class the chief complaint was of nausea and vomiting without any purging.

The sickness supervened either immediately after taking the draught, or at some longer or shorter interval during the day or night. The discharges were almost always bilious, or evidently mixed with bile. The diarrhoea was generally in proportion to the dose; from 1 to 2 drams of the tincture were followed by from 2 to 20 evacuations in the course of the 24 hours. The motions were mostly passed with acute suffering, violent colic pains in the bowels, tenesmus, and scalding of the anus. The matters passed were at first semi-fluid, but by and by they consisted in great part of a yellow and evidently bilious serum, in which floated a large quantity of whitish grains in form and colour like the ova of a fish's roe; there was also mixed with them a quantity of red matter like scrapings of

meat, and some blood more or less mixed with mucus.

Vomiting was scarcely induced by a smaller dose of the tincture than from 2 to 4 drams in a draught; it will not follow 1 dram, 2 drams, or even 3 drams administered in a large quantity of tisan. Several elements enter into the consideration of the therapeutical effects of medicines: the dose, the mode of administration, and the intervals of repetition. The effects of remedies are signally different from those generally seen when they are given in large and closely repeated doses. Three drams of tincture of colchicum in two doses, one close upon the other, produce effects which are not only more energetic, but also different from those generally witnessed.

It is obvious, therefore, that colchicum in tincture exerts its agency especially upon the bowels. Of what nature is this agency? the diarrhoea, the dysenterical character of the stools, the severe griping which follows its exhibition, do not continue as in cases in which the intestinal mucous membrane is truly inflamed; its effect is mainly to alter the secreting faculty of the intestines—the fluids habitually poured out are increased in quantity, and changed in quality.

Colchicum appears to have no effect upon the urinary secretion; and must therefore be rated from the number of diuretics.

Blood-letting.—In 19 cases of acute articular rheumatism, desiring to ascertain the effects of a somewhat energetic antiphlogistic treatment, the patients were bled at least three times each, in the course of the four first days, and cupping was further had recourse to around the affected joints, or to the region of the heart: only in two of the cases were tartar emetic and digitalis exhibited simultaneously. The quantity of blood abstracted was considerable,—large; and the venesections were repeated at short intervals. The mean stay in hospital of the patients thus treated was 14 days—about the same as when other plans of treatment were employed.

The effect of the blood-letting on the disease can always be judged of by the state of the pulse: if it becomes less frequent, and loses force and volume, and if the temperature of the surface at the same time declines, the disease will end; if the pulse continues frequent, the disease is not yet at its conclusion. Sometimes the pulse falls suddenly after the first or second bleeding and the disease appears about to be subdued; but it soon rises again to its old number, and matters go on as if there had been no prospect of amendment: the gradual and enduring fall of the pulse is the best sign of improvement; if it fall from 6 to 12 beats below its usual number, so much the better.

When the symptoms are not relieved by

the blood issuing within the first four or five days of the invasion of the disease, it is in part arrested in the abstraction of blood; the pressure then is only injurious: bellows incisions are set up in the heart and great vessels, the surface becomes drenched in sweat, the sleep is disturbed, the pulse is rapid, and the pains, far from diminishing, flit about from one joint to another, or remain obstinately fixed in those that were first attacked. The conclusion on the whole in regard to blood-letting is that in moderation it is useful, especially when practised early in the disease, within the first four days; after this, depletion by the lancet only reduces the patient, and renders his recovery more difficult.

Nitre.—Eight patients only were treated with nitre, and of the number one was affected with meningitis cerebro-spinalis, another with pneumonia. In all the rheumatism was recent and severe. The medicine was administered in doses of from 8 to 30 grammes (2 to 7½ drams) dissolved in tisane. Its influence appeared to be absolutely nil in the whole of the cases. The pains in the joints, the signs of endocarditis, underwent no kind of diminution under its influence. The pulse was not lowered, the febrile heat was not lessened by it. The quantity of urine passed in the 24 hours was not increased. In order to control the disease it was necessary in every case to have recourse to other means.

PARALYSIS OF THE ORGANS OF SENSE AFTER SCARLATINA:

RECOVERY UNDER THE USE OF IRON.

A **HEALTHY** girl, 9 years of age, whilst recovering from a trifling attack of scarlatina, and without assignable reason, was observed to be dull of hearing; by and by, to be blind, or to see very imperfectly; then to have lost all sense of taste, and finally, to be without smell; the common sensation and power of motion were unaffected. This state of affairs continued in spite of every approved plan of treatment essayed under the eyes of the best practitioners in the neighbourhood: internal medicines of all kinds, baths, sinapisms, blisters, moxas, and animal magnetism (!) The child was now put upon a course of steel, and a little wine was ordered for her, and with such good effect that in three weeks she was again restored to perfect health.—*Dr. Hoffmann, in Casper's Wochen. No. 14, April 6th, 1844.*

CHLORIDE OF MAGNESIUM.

DR. LEBERT recommends the chloride of magnesium as an agreeable, efficacious, and useful neutral aperient salt. The dose is an ounce for an adult, half an ounce for a young person: it increases appetite, pro-

motes the flow of the bile, and does not leave the bowels in a constipated state after its action.—*Archives Gén. de Médecine.*

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

ON
INJURIES AND DISEASES OF
THE SPINE.

*A Clinical Lecture,
Delivered at St. George's Hospital,*

By CÆSAR HAWKINS, Esq.
Surgeon to St. George's Hospital.

*Case 1. Dislocation of dorsal vertebra (?).
2. Partial paralysis from injury (?) or
from lead (?). 3. Curious formation on
the intervertebral substance with para-
plegia. 4. Disease of spine (?) or spinal
marrow (?). 5. Paraplegia from intem-
perate habits. 6. Disease of vertebra or
intervertebral substance. 7. Scrofulous
caries of the spine, with psoas abscess.*

IN systematic courses of lectures on surgery, given during the winter session, the student is accustomed to hear the causes, and symptoms, and consequences, of disease clearly defined; and the treatment necessary for its cure or alleviation regularly stated; and well-marked cases are selected to illustrate the more common and important complaints, while rarer maladies are briefly alluded to, or altogether omitted, owing to the short period allotted to the course. In some cases of disease the student recognises the same clearness when he begins to study them in the wards of the hospital; and he is at no loss to understand immediately the nature of the disease, and to follow the treatment which is employed; and he can test its inefficiency perhaps, or its power over the malady, according to what he has heard from his instructors. But it is not always so: he soon finds that many diseases are extremely obscure, and that the symptoms, in different cases of the same disease, vary so much, as to require corresponding variety of treatment to a much greater degree than he had been led to suppose. He thus learns

the difficulty and the importance of *diagnosis*, that is to say, of the distinctions between different kinds and varieties of disease, for which some persons' minds are much better constituted than others. You will thus find that you have, in any obscure case, to pass rapidly in review every disease which is at all likely to occur in any given organ or tissue; to lay aside, successively, the symptoms and appearances which are common to all, or to several of such diseases, and select only the more distinctive characters, till, finally, only such remain as can belong to one of these diseases, or at the most to two of them, between which you are left to choose; and you will find that much patient observation, and much practical experience too, are required in some cases, especially in the more chronic disorders of any given part of the body. I think, then, that a clinical lecture is sometimes very usefully devoted to the rarer cases, and the more obscure and difficult circumstances, which it is not the province of the systematic lecturer to dwell upon.

Among the parts of the body the disorders of which are sometimes very intricate and difficult, is the spine; in the injuries and diseases of which part you are presented with many similar symptoms, both locally as well as from interruption of the functions of the spinal marrow, whether the disease be situated in the bones or ligaments, and other textures belonging to the spinal column, or in the spinal marrow itself, or in its membranes, such as inflammation, softening, new growths, and so on; or even, sometimes, when there is no disease of these parts at all, but the cause is actually seated in the head, and the spinal functions are only secondarily impaired. I propose, then, in the lecture of to-day, to pass briefly in review a few cases of injury, or the consequences of injury, of the spine.

1. The first case I will notice is one of injury to the spinal column, without any injury of the spinal marrow within; at least its func-

tions are not in the least interfered with. It is that of John Campion, *æt.* 52, who was admitted April 15th, about ten minutes after he had been driving under an archway, and, in the act of stooping, his shoulders came in contact with the upper part of the arch, which bent him very considerably. When admitted he was in a state of collapse, and could not support the weight of his body, although there was no paralysis of any part. I saw him about an hour afterwards, at which time he was still in a state of collapse, and the dorsal vertebræ, from about the sixth to the twelfth, were bent in a curved form backwards, and there was a deeper depression between the spinous processes of the seventh and eighth vertebræ than between any of the others, and there was a great effusion of blood about the injured part and among the long muscles of the back; there was also excessive pain and tenderness, which wholly prevented the patient's moving; and he had much pain across the lower part of the chest, and difficulty of breathing, which were in part owing to previous illness.

Here, then, was an accident which is frequently fatal, but in this case is not likely to be so, as the spinal marrow seems quite safe. What is the nature of the injury? The preparations on the table shew you that the usual result of such an injury is a dislocation or fracture of the bodies of the vertebræ; and if you look to this preparation, from a patient of mine, who lived, I think, five months, so that the fracture is perfectly united, you will see that the body of the vertebræ is considerably shortened and crushed down, so that an abrupt angle is formed posteriorly by the spinous process, while a portion is driven into the spinal canal so as to lacerate the spinal marrow. In this patient (Campion), however, the curve was not an acute angle, but a segment of a circle, in which several of the vertebræ participated; it was such as you may witness in a case of common lateral curvature from weakness. The man, however, is positive that the back was straight before the accident.

Dislocation of the spine, without fracture, has been denied by some surgeons, and is generally considered very rare. I have seen it, however, several times, and there is no doubt of its occurrence. In this preparation you may see the intervertebral substance between two vertebræ quite torn up without fracture, though there was fracture of another bone in the same patient. It is, of course, most common in the neck; and you may here see a complete separation of the bodies of the fifth and sixth cervical vertebræ, from a patient of mine, in whom the bones were quite uninjured, unless there be a small portion of one articular process broken off,

which appeared to have been done after death. The displacement was sufficient to injure the spinal marrow, although the posterior longitudinal ligament was not torn; and what was curious, in the same patient, who fell from a window upon his head, the sternum also was quite broken across, though the periosteum on the inside of the bone was not injured.

Now I was inclined, at first, to believe that, in our patient, there was a laceration of the interspinal ligament, allowing the spinous processes to separate, so that the finger could be pushed between them; that this laceration might extend through the ligamentum subflavum, but that it probably did not, as the effusion of blood was so great that, if it had done so, some blood would have been likely to enter the spinal canal, and press upon the spinal marrow. If you observe the effect of my changing the position of the articular processes of these two vertebræ, you will see that, if I displace both at once, the upper part of the spine sinks forward, so that the spinous processes do not project so much as they ought to do, if you look at their line laterally; and that, if I dislocate one joint only, the upper vertebræ must be twisted, so that the line of the upper spinous processes, viewed posteriorly, does not correspond with those of the lower ones. It was quite clear that one articular process was not dislocated, and I thought, also, that the line of the spinous processes was not altered as if both were displaced. Since the blood has been absorbed and dispersed, however, there is an appearance of the upper vertebræ having sunk forwards and downwards; and as I made extension of the spine, and pressed on them without altering the curve, and without feeling any crepitus, as of broken bone, I am induced, on the whole, to think it probable that the articular processes may have been thus separated, and dislocated, though certainly without much, if any, laceration of the intervertebral substance. The great curve of so many vertebræ may have arisen from the quantity of blood driven among the long muscles, and therefore as this dispersed the curve has lessened; indeed, now it has nearly disappeared.

In the treatment of the case you will have observed that I directed him to be cupped to ten ounces on the day after the accident, as the pain was still excessive; and our notes tell us that, on the 17th, the pain was lessened after the cupping, notwithstanding the jar of an old cough, with mucopurulent expectoration, and he was directed to lie on his back on a hard mattress, with a small pillow for his head. On the 27th the depression still existed to a considerable degree, and is not yet gone (May 7th). He can now turn pretty readily in bed, but is

unable to support his weight; so that, if he sits up, he is obliged to bear the weight of the upper part of the body by resting his hands on the bed. Our notes also remark that there was, yesterday, some pain round the lower part of his chest, reaching to the spine. If there be laceration and displacement of the vertebrae from one another, we may expect that it will take some time to unite the ligaments again, and to guard against inflammation and its future consequences; and on this account I ordered him a blister, which we must repeat as often as pain requires it, or weakness remains likely to end in further mischief. With this caution there seems to be no reason why he should not become strong again.

2. In the same ward with this man is another, who has a curious local paralysis, which affects one hand and one leg.

William Cooper, *æt.* 34, admitted February 14th, after he had been buried, with two other men (who are now cured), for three hours, by the falling in of a sewer, but not in such a way as to interfere with his breathing. On admission, he was perfectly sensible, but seemed much alarmed, and shook much from this cause. He complained of pain in the left side on inspiration, but appeared to have no fracture of the ribs or any other bone. The next day he had had no sleep during the night, owing to pain and stiffness, and complained of numbness on the left side, which he attributed to his position under the gravel.

16th.—Less numbness of the side this morning; complains of a little giddiness; he has lost the power of flexing and extending the fingers of the left hand, and the power over the wrist-joint is gone also.

On the 17th, our notes say there is less numbness of the side, but he feels more pain in it, and now the right foot is found to be partially paralysed in exactly the same way as the hand; the sensibility of both the hand and foot is also impaired, so that alight pressure is not felt, and harder pressure gives a sensation of pins pricking him: the bladder and rectum are unaffected. Pulse 72, weak; but he complained of more giddiness, with pain in the head confined to the back part. For this I had him cupped on the neck to six ounces; and on the next day the notes say the pain and giddiness were relieved.

On the 20th, a curious numbed sensation in the head was spoken of, but it has not been again noticed; the partial palsy, and lessened sensibility, however, remain nearly the same now (May 7th) as at that time.

Now the question is, on what does the paralysis depend which has been the result of this accident? There has been no symptom, in the first place, making it likely that the head was injured; such partial palsy is a

very rare circumstance in any case, and he has made no complaint referrible to the brain except of the giddiness and a little pain, and the curious numbed feeling, before mentioned, which soon subsided; and the only remedy of any consequence was the small quantity of blood taken by cupping early in the case, which was done, in the uncertainty attending the injury, quite as much with reference to the spinal marrow as to the brain. Secondly, does the palsy depend on any injury of the spine? There has been, you will remember, no affection of the bladder or rectum, there is no palsy of the abdominal or thoracic muscles, there is no paraplegia, that is, no paralysis of both hands or both legs, or of all the extremities in greater or less degree, but only of the left wrist and the right foot; and such partial palsy is at least very rare after injury of the spine, though there is great irregularity at the commencement of any chronic disease of this part. Is there, then, any injury of the nerves in their course? This seems to be the feeling of the patient himself, for he says he remembers well his left wrist being doubled down, and kept there by pressure of the wood and gravel under which he was confined. Still, however, there has been no swelling like inflammation; and the pain at first was more complained of in the left side of the trunk of the body, where there is no palsy, than in the hand or foot. You may remember, however, my having more than once questioned him as to the possibility of his having been exposed to the influence of lead, for his hand drops, and has exactly the same appearance as in the partial palsy which is common in painters from the use of lead. A man was under my care, a year or so ago, with exactly the same palsy of one leg and one hand, though it usually affects the hands only; he came in for an injury of the knee, and the palsy being of only five weeks' duration, I was able to get him well. A similar paralysis arises also from other metals: I remember, for example, being myself instrumental in causing it in a woman who was ordered to have some arsenic and nitric acid applied to a large spot of lupus of several years' duration on the nates, which had resisted other remedies. The lupus was permanently cured by it, but besides the poisonous influence of the absorbed arsenic on the stomach, which subsided in a few days, there was a partial palsy and numbness of both hands and both feet, which continued in a less degree several years afterwards, when I last saw her, so that she could not work with her needle. How the metallic poison acts may be doubtful; it has been sought for in vain in the brain or spinal marrow, but has been said to have been found in the muscles; at all events it is absorbed into the circulation so as to produce the distant effects

just described from external application, which is also evident from a fact, first observed by Dr. Burton I believe, namely, that a blue line at the margin of the gums is found in those suffering from the effects of lead. Our patient has not such a line distinctly, but there are several blue spots which look suspicious: it does not appear, however, that he has had anything to do with lead, nor that he has been in any circumstances likely to have exposed him to its influence; and he is positive that there was nothing the matter with him before the accident.

In this state of uncertainty, then, as to the cause of the palsy, I have been somewhat at a loss what to prescribe. I have used, you will observe, a splint for the hand, which is of service in the dropping from lead, and I have treated the case, as if local, by friction and blisters in the course of the nerves in each extremity, which have not done much good: he has used electricity, which he thinks strengthens the limbs a little, first with sparks, but the machine has been imperfectly used, and at present in the form of galvanism, and he is now beginning to take tincture of cantharides internally, which will do good in some cases of palsy. Should he not be benefited by this treatment I think I shall employ blisters to the spine, that is, to the source of the nerves, which are of great service when partial paralysis remains after injury of the spine.

The bad consequences of injuries to the spine are sometimes very slow in their progress, and last a length of time; so that attention must be paid to any complaint of remaining pain, and stiffness, and weakness, after such accidents, in order, by the proper use of cupping and rest, followed by blisters, or setons or issues, to prevent a fatal result. The more common of the consequences of falls, or blows or strains of the spine, are caries of the bones, or ulceration of the intervertebral substance; but there may also be a variety of new growths about the spine. A very curious and rare form of alteration of structure following injury has been lately under our notice, which is not destitute of interest: it is the case of

3. Henry Senfield, *set.* 53, admitted April 17th, with paralysis of the lower extremities, almost complete, and partial paralysis of both hands. From his appearance and manner I believed that it was more a medical than a surgical case, but I admitted him, as he gave this history: "that he had a severe strain in the loins two years ago, and had lost the use of his legs about nine months, which were much wasted, but perfectly sensible to the touch." He was in the Bath Hospital for a month, two years ago (that is, soon after the accident), and was treated with cupping and issues, and was dismissed as incurable; and was treated in a similar

way in the Middlesex Hospital, and sent out thence also as incurable. On seeing him the next day, I found that there was no pain on percussion of the spine, and no projection of any part; the affection seemed confined to the anterior part of the spinal marrow, as is generally the case with caries of the spine, but the palsy was too general for any caries except in the upper part of the spine, of which there seemed no evidence; and as he had a severe cough, with much frothy mucus, and appeared very ill altogether, I transferred him to the physicians' care. He died a few days afterwards (April 27th) of inflammation of both lungs, of which the post-mortem book contains an account, but which I will not read to you, as it is irrelevant to our present subject. "The substance of the brain was very firm, but the ventricles contained a large quantity of transparent fluid." This, however, although paraplegia may arise from some diseases of the brain, did not seem likely to have occasioned the partial paraplegic symptoms of our patient, and the examination of the spine was made, the bodies of which, in front, were unaffected. On opening the canal, "the spinal marrow and its membranes were healthy," so that the case did not appear more clear; but on taking out these parts it was found "that on the posterior surface of the intervertebral cartilages were, in two or three places, small yellow, opaque, friable bodies, immediately in contact with, and apparently growing from, the intervertebral substance. The nature of the deposit could not be determined, but it certainly did not look like scrofulous matter. The largest of these bodies was situated in the lumbar region, and the smallest in the lower part of the cervical region. They projected into the spinal canal, and must have caused pressure upon the anterior column." You will see that the largest of these little bodies is not much larger than a pea, and the appearance is nearly lost by maceration in spirit; they appeared to me to be very similar to the intervertebral substance itself, a kind of hypertrophy of these bodies, but yellower, firmer, and more brittle. I may observe that their direct pressure must have had less influence on the spinal marrow than some indirect effect on the circulation of this body and its membranes. Hence it is, of course, that, in caries also, the motor power is commonly alone impaired, the effect on the spinal marrow being on its anterior part only, which is more immediately in contact with the bodies of the vertebrae, which are the seat of the caries, and the same, also, in ulceration of the intervertebral substances; and whenever there is much loss of substance, with sloughing and deficiency of vital power in the parts below the disease, you may be

sure the cause must be one which affects both columns of the spinal marrow, which caries is not likely to do. In our present case, then, we had paraplegia from an accident likely to have caused disease of the spinal bones or ligaments, affecting the nerves of motion only: the exact nature of the disease could not be known, for I never saw another instance of it. The symptoms so far differed from those of caries that I expected to have found some disease of the spinal marrow rather than of the bones, as it really proved on dissection, though of a very rare form of altered structure.

4. The next case I will bring under your notice is also one of alleged injury of the spine; but it is attended, like it, with some obscurity of symptoms, though the history seems clear enough.

William Marks, *æt.* 23, admitted on the same day as the last patient (April 17th) with supposed disease of the spine, of which he gave the following history:—About sixteen months ago he had a fall across the abdomen, and in three or four days his back became painful and stiff, and soon afterwards, in lifting a weight, he felt something snap in his back, and he could not stand for six or seven hours afterwards: he then became an out-patient for six months, and got quite well. About five weeks ago he slipped off a plank on to the side of a barge, with a sack of coals on his back, and directly he felt his back bad again, which has been getting daily worse.

On examination, the spine was straight; no pain was felt on percussion on any part of the spine. He complained chiefly of starting pains, particularly on motion, and great pain on pressing across the lower part of the loins, where the long muscles were very tensely stretched. The tongue was clean; pulse natural; and he said he was in good health. There was no numbness of the legs, but he could not stand on them on first getting out of bed, from pain in the back. The urine was natural. A day or two afterwards he complained of more pain in the back and in the shoulders, with startings and twitchings of the arms, and now he complained also of pain, on percussion, of the lower dorsal vertebræ, and of a sense of constriction across the chest and abdomen.

Here, then, we have many of the symptoms which disease of the spinal column in the part to which the pain is chiefly referred would have occasioned, but there was a greater contraction of the long muscles of the back than usual, and some affection of the upper extremities was spoken of, and although the spinal marrow is sometimes affected above the seat of the disease, yet it seldom goes so far upwards as from the loins to the axillary plexus. Again, pain is often

complained of below the real situation of the disease; so that I have many times seen setons or issues employed upon one part of the spine, while a curve has subsequently shown itself above the part supposed to be carious: still, I scarcely think there can be caries near the upper part of the back to cause the twitchings of the arms he has spoken of. Something in the man's appearance induced me to suspect there might be another cause of paraplegia, which is too frequent, namely, intemperance of life. Indulgence in wretched school habits, or over indulgence in sexual intercourse, are well known to occasion paraplegia by producing softening probably of the spinal marrow, as if the excitement of the sentient nerves, and of the reflex actions, as they are called, ended in alteration of structure of the centre of the medulla. In such cases, to distinguish them from cases of caries, you will commonly find all the extremities more or less affected, sensation impaired, and there is more spasm of muscles than is usual with ordinary caries; the mind is weakened, so that the memory is defective, and the patient is subject to low spirits and fits of crying; the countenance is pale, and the pulse feeble, and there is a downcast look of suspicion and shame, while no part of the spine can be fixed on as the exact seat of disease. I could not well put our patient into the confessional with twenty or thirty of you round the bed, and therefore directed the question to be put in a more private way, and our notes of May 3d say that he owns to masturbation, and that he has been a great rake; so that both causes may have been in operation at once.

A very well-marked instance of paraplegia from onanism was under my care not long since, which some gentlemen may remember; and I will read the notes of the case, to illustrate the diagnosis in our present case.

5. Henry Perrin, *æt.* 32, was admitted June 15th, 1842, giving the following history of the paraplegia under which he laboured. When about 16 years of age, he fell from a height of about seven feet, and struck the back of his head, and he says he was weak in the back afterwards. Seven years ago he again injured the back of his head by a fall from a load of goods, and was laid up for it some time, having blisters applied to the neck. Soon after the accident, the right arm became weaker than usual, and about three years ago the left arm also became weak; says the right leg has been weak several years, and both are so now, so that he can scarcely direct his steps. He is unable to retain his urine for any length of time, and the bowels are very costive; memory failing, and he is very nervous, and easily cries. Sight not affected, nor his hearing. Has no pain in the head. Urine

pale, acid. Sensibility lessened, so that he does not feel a blister. Temperature of axilla and groins the same, both being 100°, yet his feet feel cold. No disease of spine was apparent, and, on inquiry, he confessed to having indulged in excessive onanism from the age of 16 to 26, which practice was extended to the present time in reality, for he complained of convulsions coming on when he went to sleep, and then acknowledged that he caused the convulsions by a continuance of the same fatal habit.

You see, then, that an account of injuries and accidents likely to have occasioned disease of the spine may be given by the patient, and yet the real cause may be very different. The unfortunate victims to the propensities in question learn something of the nature of disease, and endeavour to deceive the surgeon, and conceal their delinquencies; there could be no doubt, however, of the cause of the paraplegia in this case, and some of the signs I have enumerated will generally enable you to distinguish a well-established case.

I have doubts, then, about Marks's case, and in the earlier stages of a chronic disorder, like the softening, if it be so, which dissipation creates, it is of course much more obscure than at a later period. With regard to the treatment of his case, I at first contented myself with watching the man to see if anything very decided would show itself; for in a chronic and obscure disorder it will often require more than one visit to obtain the whole history from the patient, and to observe every symptom actually present, and some fresh symptom may shew itself to decide a doubtful point. In a few days, as much pain was complained of, I had him cupped, and again on the 29th, as the pain was again increasing.

May 3d.—The notes say the pain was less, and then I ordered a blister, and repeated this yesterday, as the first had scarcely risen, and I have directed it to be kept open, and he now says he has lost the twitchings of his arms. I am treating it, in short, in a manner that is calculated to do good in either case; and if it prove, as is perhaps most probable on the whole, that there is disease of the lower part of the spine, I think it is often best to precede the use of issues by cupping, followed by one or more blisters. If, on the other hand, there should appear reason to think that my suspicions of the influence of the patient's habits are strengthened or confirmed, issues will not be called for, and a different practice may be required, which I will not enter upon.

Having brought before you these more rare or more difficult cases connected with the spine and spinal marrow, you will do well to contrast them with plain and evident cases of common disease of the spine, of

which two instances are under my care, which I will briefly allude to.

The effects of loss of substance in the spinal column are seen in the preparations on the table, in some of which there is inflammation of a healthy character, that is, without scrofulous deposit, the intervertebral substance not being at first affected, in which cases the bone remains hard, and is not much destroyed by ulceration, and parts occasionally become necrosed; in others, the bones are first filled with scrofulous matter, and so many of the bones are sometimes simultaneously carious, that the loss of figure is very great; in others, again, the intervertebral substance ulcerates first, and the disease may be, as you see, altogether confined to this structure. For practical purposes, the healthy caries, which takes place in adults for the most part, may be classed along with the ulceration of the fibrous cartilage between the bones, for I do not think you can always distinguish them from one another. Of this kind of caries an example has been afforded in a man who has been several months in the hospital.

6. Richard Nicholls, æt. 29, was admitted Sept. 6th, with angular curvature of the 7th dorsal vertebra, with weakness and pain in the loins and hips, extending down the inside of the thighs. He can walk but little, and that with pain and difficulty; and the legs start a little at times. He was in the hospital under my care seven years ago, and had issues kept open for nearly seven months; after which he was able to go about till about a year ago, when he came into the hospital under Mr. Babington, and had issues kept open for three months. He went out relieved, but not able to work; since which time he has been attended by a surgeon in the country, who has passed setons which are only just healed. On his admission this time I again ordered issues to be made, and under their use he has gradually and steadily improved, though he has not altogether lost the pain and starting, nor quite regained the power of motion: he can, however, walk much better than on his admission.

In cases of this description you can in general look forward with tolerable confidence to a cure, if the patient's constitution is in a comparatively good state; they have not much tendency to the formation of abscesses, and the disease is slow in its progress; issues have great power over the ulceration, and nothing else can be trusted to with the same satisfaction. The issues require to be kept open for a considerable time, unless the irritation is itself injurious. You will observe that seven months was the time I first employed them, and the patient then had nearly six years' freedom from disease, till a year ago a fresh accident or strain, or

some derangement of health, reproduced the disease: three months was then insufficient to check it, and I shall probably keep them open this time for a year or more, and most likely, after the pain is quite gone, I shall have them kept open for some time, even after I have thought it prudent to let him again walk about. The chief difficulty in the treatment is to ascertain when gradually increasing the motion and exercise of the part will no longer be injurious, and you must feel your way carefully.

Such cases are strongly contrasted with scrofulous caries, which affects young persons chiefly, is attended very often with little or no pain, and frequently goes on rapidly to the formation of matter in the shape of lumbar and psoas abscesses: the employment of issues and even of blisters is injurious instead of useful, by the irritation and weakness they occasion; you must trust solely or chiefly to the influence you can excite by steel, and other tonics, on the general health, except in some young persons in whom the pain is greater than usual, and the disease perhaps is less scrofulous, in whom leeches once or twice, or one or two blisters at first, relieve the inflammation without weakening much; after which, rest, and the protection afforded by light stays, are the only local remedies you are to have recourse to. An example of scrofulous caries is afforded you in a girl now in the hospital with a large psoas abscess.

7. Eliza Grey, æt. 18, admitted March 20th with a fluctuating tumor in the right femoral region. She was in the hospital last year under my care for fistula lacrymalis of three years' duration, and went out in August last, wearing a style in the duct. Soon after she went out, she says, she jumped off a window-sill about six feet, and fell on her side, which has caused lameness of the right hip ever since, and at this time she first perceived pain in the back, and shortly afterwards a swelling appeared in the groin. 'Here is, our notes say, a fluctuating swelling about three inches in diameter just below Poupert's ligament, and fluctuation can be felt by pressing above, that is, the iliac fossa is full of matter, communicating under the ligament with the swelling in the groin. She complains of pain on percussion of the lower dorsal and upper lumbar vertebrae, where there is an apparent but slight lateral curvature to the left, and she complains of pain in the hip when walking, which appeared to be owing to the proximity of the abscess. The patient is of scrofulous appearance, and has a scrofulous abscess of a cervical gland, and another on the left cheek, in addition to that of the lacrymal sac.

There is no doubt, then, of the nature of the disease in this case; that there is caries

of scrofulous origin in the spine, ending in abscess. Psoas abscess, in fact, scarcely ever takes place without your finding some disease of the bones of the spine, though it used to be supposed that it did so not unfrequently; and of course, too, when of such a size as in our patient, the disease is frequently fatal.

The only practical point I shall speak of in her case regards the abscess: are you to open them? and if so, in what manner is it to be done? It is observed that opening these large abscesses is not unfrequently succeeded by severe constitutional derangement—rigors, fever, secondary abscesses, and death; and it has been supposed that this arises from the entrance of air, and that opening the abscesses, and immediately closing them again, is likely to prevent these dangers. My own opinion is, that the mode of opening them is of much less importance than has been imagined; that the symptoms depend not on the entrance of air, but on the condition of the abscesses, on the sac being inflamed, on the secretion being unhealthy from communication with bone or mixture of blood, especially if you squeeze the abscess, and thus injure the blood-vessels. You will, therefore, often see exactly the same symptoms when the sac is in this state, without its being opened at all, or whether you close it or leave it open after you have punctured it. I remember a young woman who had a lumbar abscess, with rigors, and fever, and pain, in her side, and the sac was red, and increasing rapidly, and I said to the students, I don't like meddling with this abscess, for it is in such a state that I dare say she will have absorption of foul matter and secondary deposits. I was obliged, however, to do it, and, as I anticipated, she had on the third day rigors and perspiration, and died in a few days more with secondary deposits. I do not wish you to understand that the air entering a cavity may never do harm; you have only to compare a simple and compound fracture to see that it may do so; and accordingly, if there is blood mixed with pus in the abscess, the access of air is likely to assist its putrefaction, and make the secretion foul and poisonous. When your patient has rigor or perspiration or fever before you are obliged to open a large abscess, it is better to make a free opening, and let it remain open afterwards; if, again, you find the matter is dark coloured or offensive, or blood escapes into the abscess, do not close the puncture, lest it inflame subsequently, and foul pus be confined; but if, on the other hand, you open a psoas abscess on account of its size, or its rapid increase, and there are no constitutional signs of inflammation in the sac, and if when you let out all the pus, you find that it is healthy, and free

from blood or offensive smell, there is no reason why you may not open it in the way recommended by Mr. Abernethy, and it may possibly contract, as I have sometimes seen it do, and by rest and other measures be prevented from filling again. If you are obliged to puncture it again, you may at a future time let it remain permanently open.

As there seemed no reason against it in this girl, who had slight chills only at night, and no distinct fever, and as the abscess was increasing, I punctured it with a trocar, letting out on April 6th about ten ounces of healthy pus, and closed the orifice. Again, on the 15th, I evacuated about twenty ounces of pus, thinner than before, and with a few lumps of cheesy matter. Perhaps I may do the same again; or, if it seems to fill rapidly, I may leave it open to discharge constantly. The case is, however, a bad one, owing to her state of health.

[May 10th.—Mr. Hawkins again let out about twenty ounces of pus, and on neither occasion was any fever produced.]

PUERPERAL CONVULSIONS:

THEIR FREQUENT ASSOCIATION WITH ALBUMINOUS URINE.*

DR. LEVER informs us that, out of 7,404 women, attended between the years 1834 and 1843, by the pupils attached to the Lying-in Charity of Guy's Hospital, 14 cases of puerperal convulsions occurred,—3 in the anæmic, 11 in the sthenic form, of which latter 2 proved fatal. The cases are given in detail: in 7 the children were born by the natural efforts, in 3 the delivery was effected by the forceps, in 2 by version, and in a twin case (which recovered, and in which the convulsions preceded and continued after delivery,) the first child was also extracted by the forceps, and the second by version. In the remaining case, one of the anæmic form, where the seizure occurred three days after delivery, there was partial presentation of the placenta, with a footling and funis presentation of the child, which had been dead some days. 8 women were primiparæ. In 2 the convulsions appeared *before*, in 10 *during* labour, and in 2 not till after delivery. 11 of the 15 children produced were born alive, including 3 extracted by the forceps, and 1, the second of twins, by version.

Dr. Lever observes that the symptoms

which marked the course, and the principles which guided the treatment, of these cases, presented no new or extraordinary feature; but the coincidence of an albuminous condition of the urine, in nine out of ten cases in which it was examined, is a *fact*, so far as his investigations and inquiries have extended, which has not been previously remarked.

Having met with a case of convulsions where, from the previous existence of anasarca symptoms, it was regarded as pregnancy complicated with granular disease of the kidney, but where the woman recovered, and all traces of albumen in the urine disappeared, Dr. Lever was led "to suppose that the albuminous condition of the urine depended upon some transient cause, probably connected with the state of gestation itself." He therefore carefully examined the urine in all the cases of puerperal convulsions that subsequently occurred in the Lying-in Charity and in private practice, and found it albuminous at the time of the convulsion *in every case but one*, in which inflammation of the membranes of the brain with considerable effusion was found after death. He further tested the urine drawn off by the catheter during labour, and with precautions to prevent the admixture of vaginal secretion, in more than fifty women, and the result was, "that in *no* case was albumen detected except where there had been convulsions, or their recognized premonitory symptoms. Urea was sought for in the blood in one instance, but not detected." Dr. Lever's experience leads him to the conclusion, that "cases of convulsions complicated with an albuminous condition of the urine are divisible into two forms: in the one the urine is *albuminous during pregnancy*, of which there are external evidences, as œdema of the face, eyelids, hands, &c. In such cases the convulsions will be more violent, will last for a long time after delivery, and the urine will long retain its albuminous properties. In the second variety the urine becomes *albuminous during the labour*. The albumen is less abundant, and speedily disappears after delivery. The fits are less violent, and seldom reappear after the labour has been completed, but if they do it is in a milder form, unless complicated with lesion of the brain.

* Guy's Hospital Reports, 2d Series, No. 2.

Dr. Lever considers that Mr. Robinson, in his "Inquiry into the Nature and Pathology of Granular Disease of the Kidney, and its Mode of Action in producing Albuminous Urine," has satisfactorily proved that causes which induce congestion of the kidney by preventing or obstructing the return of blood through its veins, as abdominal tumors, &c. will produce renal congestion, and is of opinion that the gravid condition of the uterus by its pressure prevents the return of the blood through the emulgent veins, causes renal congestion, and the consequent albuminous condition of the urine. This congestion may take place towards the close of pregnancy, or it may not be excited, and the albuminous urine present, till the onset and progress of labour. He further remarks, that great similitude exists in the appearances presented by females attacked with eclampsia, and those observed in persons affected with albuminaria. In neither case do the convulsions strictly deserve the term "epileptic." Epilepsy is a chronic disease, while puerperal convulsions, and the convulsions which attend the morbus Brightii, are of a clonic character.

The treatment advised by Dr. Lever in the sthenic form consists of active depletion, the prompt and regular exhibition of tartarized antimony and purgatives, because, he remarks, "it is no unusual thing to find large scybala evacuated, even though the bowels may have been daily relieved." Mercury requires great caution, as the system is very readily affected in puerperal convulsions attended with albuminous urine, and when its specific effects are produced, the diarrhoea, pyalism, and consequent debility, are extremely distressing, as well as difficult to remedy.

He deprecates artificial dilatation of the os uteri (which may induce a convulsion), is no advocate for rupturing the membranes and inducing premature labour, and is altogether opposed to incisions in the vaginal portion of the os uteri, as recommended by Velpeau, but strongly advises delivery as soon as the state of the parts through which the child has to pass will permit. If the membranes are unbroken, the os uteri soft and dilatable, and the external parts lax and moist, version may be performed, but unless circumstances

call for immediate delivery he would rather wait till the head can be seized by the forceps or vectis.

DR. POWER ON THE THEORY OF MENSTRUATION.

To the Editor of the Medical Gazette.

SIR,

A PAPER, bearing the signature of Anglus, has lately appeared in your journal, which professes to give a faithful statement of the progress of discovery in the true theory of menstruation. As I have reason to regard that statement imperfect, and calculated to detract from my own claim, or merit, as the original promulgator of the theory to which it alludes, I rely on your sense of justice to insert in the forthcoming number of the MEDICAL GAZETTE the following remarks.

Although my Essay on the subject was not published until the year 1821, the theory to which it relates virtually dates back as far as 1807, when I was a student in the Windmill Street School of Anatomy, conducted by the late Mr. James Wilson. In a form substantially the same it was at that time submitted to Mr. Wilson, and also to the late Dr. Clark, or his brother the present Sir Charles Clark, who were lecturing on midwifery conjointly, in John Street, Golden Square; I am not at this distance of time certain to which, but I believe to the latter. These gentlemen pronounced my views "ingenious," but they did not appear to excite much interest in their minds. It must be recollected, however, that at that period the knowledge of physiology was much circumscribed by the high authorities of Haller, Hunter, and some few other leading spirits; to depart from whose opinions, or to attempt to advance beyond them, was apt to be regarded as a species of presumption; that principle of practical investigation, which has since characterized our profession, then only partially existed. This was a state of things which would naturally tend to discourage what might be regarded by those gentlemen as hypothetical innovation; and yet, I well recollect that Mr. Wilson, in his lecture on the subject, stated that the nature and uses of

menstruation comprised one of those *arcana*, the discovery of which would immortalize a man, but which, during two thousand years, had received no additional light; and I also remember that this dictum was the main spring of my own attempts to unravel its causes.

The opinions I was in consequence led to entertain were the results of much reading and severe reflection; and I am not ashamed to admit that they were chiefly obtained from these sources, and by attentive comparison of causes and effects, and by no means, as Anglus has asserted, from analogy alone. I did not neglect to examine the female ovaria, where I found abundance of those appearances which Harvey, Hunter, and others, termed *ova*, *corpora lutea*—true or false—although they did not refine so far as to draw distinctions between the former and ovules, Graafian vesicles, &c., &c.; anatomy had not then proceeded thus far.

It was my fortune for the next thirteen years to be engaged in country practice, where the prejudices against the examination of the human body after death precluded every chance of confirming my views by the inspection of ovaria.

When my opinions were published in 1821 they were perfectly novel and original; for it is impossible to regard the observation of Kerkringius as unfolding any view analogous with them; his opinions evidently corresponded with those of Harvey, Fallopius, De Graaf, and others, who, about that period, laboured much, and successfully, to show the origin of the human *fœtus ab ovo*, with the additional observations that "*aliquando fœminæ deiciunt hæc ova imprimis tempore menstruarii*," and there is no ground for imagining that he contemplated any co-relation between these *ova* and menstruation in the production of the latter process, of the true nature of which he was as ignorant as any of his predecessors or contemporaries.

Nor is the recited case of Cruikshank more to the point: although this distinguished physiologist detected a laceration on an ovary from which he "suspected an ovum had descended into the fallopian tube, and been then washed out by the menstrual blood," he

never regarded this ovum and the menstruating action as connected together in the chain of cause and effect; on the contrary, he evidently considers the ovum in question to have been detached as a sequela of impregnation, and its removal by the menstruating process as an accidental and extraordinary occurrence; nor did he attempt to found upon the fact any theory of menstruation.

What, then, do the observations of Anglus on this case amount to? Why, that Dr. Power has not taken notice of a predecessor who had not one idea in common with his own, but who had observed a fact, the account of which, at the time of publishing his theory, Dr. Power had probably never met with, and which had he claimed to have done so, would have assisted in the confirmation of that theory; and, ergo, that Dr. Power is entitled to a less portion of merit than he would otherwise have had a claim to!

As it is most gratifying to an ardent mind to receive encouragement when it believes that it has suggested an important improvement, so it is proportionately depressing when its efforts are met by neglect or ridicule. My fortune has been to be virtually encountered with both: for nearly forty years that have passed since the promulgation of opinions, which it now appears were not devoid of truth and value, not one cheering word escaped from the professional world around me; on the contrary, when my Essay was published, in 1821, the notice taken of it by the leading periodicals held its author up to contempt and ridicule. One regrets that I should have occupied my time, which might have been so much better employed in useful practical pursuits, in building up such vague hypotheses*. Another, after supporting a series of hypercritical observations by imperfect and garbled extracts, not only refused to admit any reply, but, in a note appended to a succeeding number, indulged in such grossly indelicate language, that I should be ashamed to sully your pages by quoting it†. Oh! the baneful, the pernicious effects on science which may be produced by the ignorance, stupidity, or incapacity of

* London Medical Repository, 1821.

† London Medical and Physical Journal, 1821.

those who pretend to direct public opinion! Had the journalists simply said, what the results would have justified, "the opinions of the author are novel and peculiar, but require patient investigation to confirm them," it is possible that no opportunity would have been afforded, in this particular instance, either to Dr. Robert Lee, or M. Gendrin, or any other individual, to say a word on the subject.

Anglus has stated that, in 1831, ten years after its publication, "Dr. Power's hypothesis had nearly sunk into oblivion." This was a fate by no means improbable, considering the apathy with which it was received by the profession, but which, had it happened, would not have redounded to its credit. The assertion, however, is not true, nor could it possibly be so, inasmuch as during the whole of the period mentioned its author never ceased to instil his "*hypothesis*" into the minds of numerous pupils, many of whom were fully impressed with the opinion of its value and importance.

It may be asked why, during this period of ten or more years, when I occupied the station of a lecturer in London, I did not find opportunities of more fully illustrating and confirming my theory, particularly as in the preface to my Essay I have admitted, that, notwithstanding it appears to be well supported by many well-established facts, it was not likely to be deemed a perfect explanation until a better intelligence was gained of the nature of the generative, and more particularly of the ovarian actions. I might reply, that whatever opportunities offered themselves, calculated per chance, in the course of anatomical research, to afford such confirmations, the probability was comparatively small of my meeting with them, unaided as I was by any sympathy or co-operation on the part of the profession: even, in this respect, what few notes of dissections I was enabled to make, together with the whole of my books and papers, were subsequently destroyed by fire. But other reasons or circumstances influenced me: I already considered the theory sufficiently "supported by well-established facts" to ensure its vitality; and discouraged, if not disgusted, by the reception it had met with, I determined to leave it to its fate, until future and more enlightened times should admit

it among the acknowledged facts of medical science; in short, Mr. Editor, I was in some measure guilty of the unnatural conduct of abandoning my offspring; but I at the same time felt convinced it would ultimately, and that probably better without my assistance, make its way in the world: still, *it is the child of my own brain*, and I may be pardoned for feeling sufficiently proud of it, not to be willing, contentedly, to relinquish my paternity to another.

In the year 1832, I quitted London, and resided for some years on the Continent, but although thus virtually withdrawn from the profession, I never ceased to be an attentive observer of the progress of opinion, or relinquished the conviction that my views, founded, as I believed them to be, in truth, would ultimately triumph. I must confess that I have been not a little amused, during this later period, at the attempts of individuals to assume to themselves the originality of discovery, and especially of the French physiologists, who I have reason to believe might have derived their first ideas from some of my pupils, inasmuch as several of them, about the years 1827 and 1828, studied in the schools of Paris, and one of them in particular, Dr. Horner, founded his inaugural thesis, in Edinburgh, upon the subject of the ovum, and, with slight modifications, adopted my doctrine.

Anglus has farther said, "Dr. Power may be permitted to enjoy all the glory of having propounded a theory, whilst it is remembered, at the same time, that of that theory he did not furnish one satisfactory proof:" he then adds, that M. Gendrin "both propounded and proved the truth of the theory."

Now, sir, holding myself, as respects any controversy on the present subject, as standing perfectly isolated and alone, it is scarcely requisite for me to say that I have no wish to detract, in the slightest degree, from the merits of M. Gendrin and his associates; nor will I assert that their inspirations have not been derived from their own genuine sources; but this much I will say, and I think it must be admitted, that the theory they have "propounded" had been *fully* propounded before; and I will add, that I cannot allow the relative quantity of merit which Anglus obviously appears desirous to attach to them and to myself respectively,

namely, that mine is of a minor, theirs of a major kind.

I beg to inquire whether it could be held as a *minor merit* to have detected, through the darkness and ignorance of ages, correct glimpses of an important fact, or of an unknown world? To which, in the opinion of posterity, has the highest meed of honour been attributed, to Columbus or Americus Vesputius? The former, by his reasoning powers, and the inferences deduced from analogy, propounded the existence of a new world, the confines of which it was his fate only to touch upon; the other, availing himself of these views and experience, actually succeeded in reaching that world: does any one contend that he was justified in having made it his own? I have not the vanity to presume that the parallel is perfect; but I do contend that, in consequence of a severe study of the various *facts* which my opportunities and the state of medical science at the time permitted, I not only propounded a theory, but went far beyond its confines, and declared virtually a variety of facts connected with it which subsequent physiologists have done little more than confirm; nay, I have gone still farther, and have advanced additional views which are probably equally true, and which others appear not yet to have touched upon; I allude to the connection between menstruation and gestation, and the peculiar manner in which, in the human subject, the impregnated ovum becomes attached to the uterus by the intervention of the decidua membrane.

I regret to feel myself compelled to such egotisms; they are foreign to my nature; and I defy the world to shew that I have ever assumed to myself any undue proportion of "glory" with respect to what I have done: this I cannot better prove than by the following extract from my notes of the concluding part of the lecture I was in the habit of delivering to my pupils on the subject, and which, from his observations respecting "publicity by lecture," I infer Anglus will not consider otherwise than legitimate.

"It would be presumptuous in me to imagine that so humble an individual as myself had succeeded in explaining satisfactorily the nature of a function which has, for at least two thousand years, in vain excited the attention of

the greatest philosophers and physiologists. All I pretend to is, that I may have offered a theory which has reason and probability in its favour. You may, perhaps, regard it as unworthy of your notice, or you may receive it as of at least equal value with its predecessors, or possibly you may admit it with myself as affording a more probable explanation than any previous hypothesis has given. In any of these cases I have one favour to solicit; namely, that you will bestow upon it an attentive examination, and that, should the result be in its favour, you will not hesitate to maintain it with that ardour and pertinacity which science ought ever to expect from its friends and cultivators. Farther, should you be induced to pursue its investigation, I hesitate not to say an opportunity offers of distinguishing yourselves amongst the improvers of medical science."

I might extend my remarks much farther, but that I am unwilling to trespass too much on your valuable pages; I will therefore conclude with requesting those who may feel induced to take an interest in the subject to examine attentively the full meanings and contexts of the opinions advanced in my Essay, so as to avoid the errors which partial extracts are liable to engender; and particularly to take into account the state of medical science at the period when it was published, its nomenclature and terminology; important misrepresentations having been propagated in these respects*. Should they then think proper to regard my views as mere "conjecture" and "hypothesis," and the arguments by which they are supported as unwarranted "statements" for which I had "no grounds," I must be content to bow to the decision, however inconsistent I may deem it with the dictates of reason and justice, and the previous usages of philosophical research.

I have the honour to be, sir,

Your obedient servant,

JOHN POWER.

9, Great Queen Street, Westminster,
May 7th, 1844.

[We have the greatest pleasure in giving insertion to the preceding ex-

* Vide the observations contained in the *Cyclopædia of Practical Medicine*, Vol. iii. p. 237, respecting the term ovum, and contrast them with the descriptions in my *Essay on the Female Economy*, pp. 11, 13, 14, and 15.

cellent letter from Dr. Power. We have even felt it a duty to him, and through the respect in which we hold originality, to refer to his work entitled *Essays on the Female Economy*, published in the year 1821; and find it equally ingenious and creditable to him as a physiologist as it is learnedly and candidly written. Had there been less of speculative ingenuity—a quality, however, which we would not be held for a moment as undervaluing, for indeed we believe it to be one of the truest attributes of genius, which, out of known facts and foregone conclusions, sees intuitively, as it were, facts and inferences that are yet in the womb of time—we say, had there been less of speculative ingenuity in Dr. Power's work, his views would probably have attracted more attention at the time, and his merits in the interesting subject of which he treats have been now unquestioned. Dr. Power's very comprehensive generalizations, however, led him to sum up his views in a certain general proposition, which is always quoted in some sort against him, and if not with the purpose of obscuring his views in regard to the cause of menstruation, at least with such an effect. The general proposition alluded to is the following:—"The efficient cause of menstruation may be defined 'an imperfect or disappointed action of the uterus in the formation of the *membrana decidua*, which is requisite for its connection with the impregnated ovum,'" p. 28. But when we go back, and find our ingenious author insisting (p. 13) that in every female arrived at puberty the generative process is proceeding in a regular and uniform series of progressive actions, to produce an ovum, and to prepare for the removal of that ovum; that, precisely as in the hen or pullet (pp. 14 and 15), "ova are also found in the enlarged ovaria of the human adult female, in different states of perfection," and "that in women who have never been pregnant, corpora lutea, and cavities which have been supposed previously to contain ova, have been detected," "that menstruation is a farther link in the chain of these progressive actions;" "that it is not only probable, but certain, that these actions are not confined to the ovaria, and the consequent production of ova, but that the whole female economy sympathises in the work that

is there going on," "that *the uterus in particular enlarges, its vascular action increases, and the phenomenon of menstruation succeeds*;" we cannot hesitate to do Dr. Power the justice to say that he left little for any one who came after him to accomplish. He may be said to have demonstrated the necessity of the thing, which has since been shewn as in a mirror. See how he carries out the idea above alluded to in the very next page: "In proportion as the ovum acquires a state of maturity in the ovarium, the uterus undergoes a corresponding preparation for its reception. Its vascular action is increased in a degree tending to a state of inflammation, and it wants but the additional stimulus of impregnation to determine it to the production of the deciduous secretion so requisite for the proper connection with the ovum; if, however, the stimulus of impregnation is denied, this increased action is not carried to a sufficient height to produce properly that effect; nevertheless, it is sufficient to give rise to the effusion of a fluid, *which fluid is the menstrual fluid* (p. 19). Here we see a train of thought which connected the fact of menstruation with "a disappointed action of the uterus in the formation of a deciduous membrane;" this disappointed action, however, is evidently the last link in the chain of effects which had the production and arrival at maturity of an ovarian ovum as their efficient cause.

We beg to refer Dr. Power to a short address "To our Friends," in our last number but one, for solace in the neglect he has experienced—in the attempts that have been made either to detract from, or to strip him of, the honour that is fairly his due. We have farther pleasure in informing him that the same messenger who brought us his own letter, brought us a powerful communication from Glasgow—we observe each other's movements now at the antipodes,—in which Justice herself fairly throws away the scabbard in his favour; and which worthy letter of "Justitia" would have been published, had not Dr. Power's own appeared to us preferable, and afforded us the agreeable occasion of making the above comment on his old and very original work.—
ED. GAZ.]

CASES OF
DIABETES MELLITUS :

WITH PRECISE OBSERVATIONS CONCERNING
THE INFLUENCE OF ANIMAL DIET UPON
THE URINE.

BY JOHN PERCY, M.D. Edin.

Physician to Queen's Hospital, and Professor of
Organic Chemistry, Queen's College,
Birmingham.

(For the *London Medical Gazette*.)

[Continued from page 154.]

CASE II.—At the latter end of November 1843, in conjunction with my friend Mr. Wickenden, I attended Mr. —, a gentleman of middle age, of high stature, of moderately robust frame, and of sedentary occupation. He was affected with confirmed diabetes mellitus. On careful inquiry, it was impossible to ascertain the period when the disease first appeared. The symptom which principally attracted the attention of the patient and his friends was emaciation: he had lost 40 lbs. in weight. He had, however, observed that he passed urine in larger quantity and more frequently than natural, and had complained of thirst. He felt quite well, with the exception of being occasionally irritable without assignable cause. Having been under the judicious treatment of Mr. W. for some time before I saw him, the thirst had been relieved, the urine reduced in quantity as well as in specific gravity (which at first amounted to 1047), and the condition of the skin improved. His general health had always been good, and he had never had any serious illness. His appetite was natural; tongue clean, but not preternaturally red; no sponginess of the gums; skin warm and moist; pulse regular, of tolerable strength; no phymosis or irritation about the urethra; bowels regular; no uneasy sensation at the epigastrium either before or after taking food; no peculiar taste. No hereditary predisposition. He had never been exposed to extreme alternations of temperature. The warm bath occasionally, and a diet principally of animal matter, had been prescribed; but bread and potatoes were allowed in reduced proportion. We determined to recommend an exclusively animal diet, forbidding all amylaceous matter, and prescribing sulphate of iron, with a small quantity of

opium. The patient immediately concurred in our recommendation, and has rigidly restricted himself to the diet enjoined. As he had always been accustomed to generous living, we allowed a small quantity of brandy and water daily. We have since occasionally prescribed other medicines, but not such as can be supposed in any material degree to influence the disease. The patient has continued to enjoy comfortable health, and to pursue without interruption his wonted avocation. He can take exercise without fatigue, even to the extent of ten or eleven miles occasionally. His muscular tissue is tolerably firm; but it must not be omitted that his weight has not increased: it has occasionally varied a little, but has not at present suffered further and permanent decrease; and, what is remarkable, the patient has never, with one or two exceptions, been disturbed in the night with calls to pass urine.

Chemical Observations respecting the Urine.

Dec. 1st.—Urine received last night. Colour straw; odour urinous; reddens litmus; copious deposit of pale flesh-red colour, consisting of urate of ammonia mixed with lozenge-shaped crystals of uric acid. These crystals were immediately detected under the microscope after dissolving out the urate of ammonia by warm water and removing the solution by a pipette. Specific gravity 1036. Reddish brown precipitate by Trommer's copper test. To some of this urine I added an equal volume of nitric acid; on the following morning no crystallization of nitrate of urea had occurred. The urine, reduced by evaporation to the consistence of syrup, evolved a strong urinous odour, had a saline, not sweet, taste, and became, by the addition of nitric acid, a crystalline magma. It fermented readily with yeast, in a tube over mercury. The quantity of urine passed daily, so far as I could ascertain, was not much more than in health, not exceeding four pints.

6th.—Colour pale brown. Perfectly transparent, with the exception of the usual delicate mucous cloud at the bottom; but, after standing two days, it had deposited pale reddish brown urate of ammonia mixed with small dark coloured crystals of uric acid.

Odour urinous; reddens litmus; specific gravity, 1021.

Put, to ferment, 1000·0 grains mixed with yeast in a two-necked bottle, connected, as before described, with Liebig's potass apparatus,—

Dec. 8, weighed . . . 605·40

Dec. 6, weighed . . . 605·39

0·01

No sugar, therefore, was present. In order to verify the result, I introduced f 3ss. of the same urine, mixed with a minute portion of yeast, into a graduated receiver over mercury. Three days afterwards not the smallest evolution of gas had occurred.

The result was further confirmed by the application of Trommer's test, which revealed not the smallest trace of sugar.

Analysis of 1000 grains.

Solid matter	47·78
Water	952·22
Urea	21·92
Uric acid and indeterminate } organic matter	20·14
Chlorides	0·86
Sulphate, carbonate, and soluble } phosphate	3·94
Earthy phosphates	0·92

1000·00

The weight of solid matter was ascertained by drying in vacuo over sulphuric acid during ten days. By evaporation over the steam-bath, a brown mass of acicular crystals was obtained.

11th.—Urine passed last night. Colour of ordinary urine. Odour strongly urinous. At first clear, without deposit; but, on standing, flocculent urate of ammonia was separated. Specific gravity, 1019. Quantity of liquid drunk during last twenty-four hours, 66 fluid ounces; quantity of urine voided during the same period, 64 fluid ounces.

16th.—Urine passed this evening. Has taken gluten bread, obtained from Mr. Morson's, London, during the last few days. Colour of ordinary urine. Specific gravity, 1020. No evolution of gas, by admixture with yeast, after standing in a warm place three days.

23d.—Urine passed this morning. Has taken daily, during the last week, a small quantity of common bread and potatoe. Colour, pale brown. At first without sediment, but, after standing a day or two, deposited pale brown

urate of ammonia. Specific gravity, 1039; temp. 62° Fah.

1000 parts contained 39·1 of sugar.

27th.—Urine received yesterday. The patient having, since the last examination, been again restricted to an exclusively animal diet, except in so far as milk may be regarded as containing a principle, lactine, analogous to vegetable matter. Pale brown flocculent deposit of urate of ammonia. Specific gravity, 1025; temp. 58° Fah. No trace of sugar detected by the addition of yeast in the usual manner.

Jan. 4th (1844).—Has been again taking gluten bread. Colour of ordinary urine. Pale red deposit of urate of ammonia. Specific gravity, 1038; temp. 53° Fah. Fermented readily with yeast over mercury.

15th.—Urine received to-day. Straw coloured. Mucous cloud as usual. Specific gravity, 1029; temp. 52° Fah. Fermented readily with yeast.

Liquid drunk in twenty-four hours, 64 ounces; urine voided during the same period, 48 ounces.

Feb. 6th.—Urine received yesterday. Pale. Deposit of uric acid and urate of ammonia. Specific gravity 1035; temp. 58° Fah.

1000 parts contained 23·2 of sugar.

12th.—Urine received this morning. Flocculent deposit of uric acid and urate of ammonia. Specific gravity, 1035; temp. 53° Fah.

Analysis of 1000 grains.

Solid matter	81·70
Water	918·30
Urea	30·32
Uric acid	0·26
Sugar	17·15
Indeterminate organic matter	23·77
Chlorine; carbonic, phosphoric } (copious), and sulphuric acids;	8·82
potass and soda	
Earthy phosphate	1·38
Silica, trace of.	

1000·00

The weight of solid matter was determined by evaporation in vacuo over sulphuric acid during twelve days. The urea was separated from urine which had been fermented. The weight of sugar was deduced, as usual, from the volume of carbonic acid liberated from 100 grains of urine fermented over mercury. The incineration was conducted with great facility, and a

perfectly white ash was obtained. The incineration of the fixed residuum of ordinary diabetic urine is an extremely troublesome process.

Feb. 20th.—Urine received yesterday; the patient still continuing restricted to the same animal diet. Pale brown; strongly urinous smell; deposit of urate of ammonia; specific gravity, 1033; temp. 56° Fah.

Quantity of liquid drunk in twenty-four hours, 50 fluid ounces; quantity of urine passed, 60 fluid ounces.

26th.—Characters as before. Specific gravity, 1034; temp. 57° Fah.

March 9th.—Pale brown; specific gravity, 1034; deposit of uric acid and urate of ammonia.

Quantity of liquid drunk in twenty-four hours, 48 fluid ounces; quantity of urine passed, 52 fluid ounces.

1000 parts contained, of sugar, 30·45

Ditto ditto of urea, 27·92

CASE III.—Feb. —. In conjunction with Mr. T. Chavasse, I visited Mr. —, a fine portly looking man, of ruddy complexion. He was about 60 years of age, and must have weighed, when in health, not less than 16 or 17 stones. With the exception of slight debility, he feels as well as ever. His countenance is cheerful, and not at all indicative of disease. He has lost flesh considerably; yet he is still corpulent. He has no accurate knowledge of the extent to which he is reduced, as he has never been weighed in his life. He thinks he remarked thirst and incipient loss of flesh two years ago; at that time, also, he rose frequently in the night to pass urine, but this symptom might have been occasioned by a stricture with which he is affected. His appetite was at first increased, but of late has been impaired. Had never been exposed to sudden alternations of temperature. No hereditary predisposition. A nitric acid mixture had been prescribed for him, but no material alteration in his diet had been enjoined, bread, potatoe, and porter being freely allowed.

Present symptoms.—Thirst; dryness of mouth and fauces, tongue white and coated; gums spongy and receding from the teeth; appetite not increased; no perspiration, not even in the axillæ, though in health he was accustomed to perspire freely; skin dry, yet not particularly harsh; slight dimness of

vision; no numbness in any part; passes about seven or eight quarts of clear urine in twenty-four hours; bowels frequently confined; stools lighter coloured than natural; pulse of moderate strength, yet somewhat languid; cannot walk as formerly without fatigue; occasional pain across the loins; has always had occasional cough; is not at all fretful, his countenance being expressive of good humour.

We recommended that his allowance of bread should be reduced to eight ounces daily, and that it should be made with flour from which a portion of the starch had been washed out. No other vegetable matter. Beef or mutton with fat, and beef-tea; oysters; custard puddings, made of egg and milk, without flour; new milk; fish; and any other convenient animal food. No malt liquor, but only weak brandy and water occasionally, in consideration of his previous habit of living.

℞ Sulphatis Ferri, gr. ij.; Extr. Rhei, Extr. Gentianæ, aa gr. jss. M. ft. pilula. Capiat j. talem ter die.

℞ Ammon. Carb. 3j.; Sp. Lavand. Co. f3ij.; M. Camphoræ, f3viij. M. ft. mist. Capiat f3j. ter indies.

Examination of the urine.—Colour, pale straw. Clear, with the exception of the usual mucous cloud. Specific gravity, 1039°; temp. 50° Fah.

Analysis of 1000 grains.

Solid matter	101·10
Water	898·90
Urea	2·39
Sugar	79·10
Uric acid and indeterminate } organic matter	16·74
Chlorine; carbonic, sulphuric, and phosphoric acids; potass and soda } Earthy phosphate	2·78
	0·09
	1000·00

100·0 grains of this urine, dried in vacuo over sulphuric acid during 14 days, left 10·110 of pale brown residue. The urea was determined in the usual manner from 500·0 grains of the fermented urine. As the patient passed about six times more urine than natural in 24 hours (estimating the natural quantity at 42 ounces), we may expect to find only one-sixth of the respective quantities of normal ingredients. Ac-

ordingly, by multiplying the urea and saline matter by 6, we have,—

Urea	14.34
Soluble salts	16.68
Earthy phosphate	0.54

Hence we perceive that the amount of these ingredients excreted daily was pretty nearly the same as in health.

March 1st.—Thirst diminished. Urine reduced to 7 or 8 pints daily. Recommended a further decrease in the bread to 6 ounces, urgently persuading the patient not to deviate from the prescribed kind of diet.

4th.—Urine received yesterday. Clear. A small quantity of red crystalline deposit of uric acid. Not so pale as before. Specific gravity, 1038; temp. 58° Fah.

8th.—Improvement continues. Urine reduced in quantity. Pale brown. Odour urinous. Specific gravity, 1031; temp. 57° Fah. Acid reaction. A small quantity of crystalline deposit of uric acid.

1000 grains yielded, of sugar, 49.7

Ditto ditto of urea, 9.76

I repeat that any conclusions which may be drawn from the preceding cases will be reserved for a future communication.*

[To be continued.]

REPORT ON THE ROYAL MATERNITY CHARITY.

By F. H. RAMSBOTHAM, M.D.

(For the London Medical Gazette.)

[Continued from p. 197.]

DURING the year 1834, there were delivered, in the Eastern District of the Royal Maternity Charity, under the superintendence of Dr. F. H. Ramsbotham,—

2447 women—Of which cases

26 were twins—about 1 in every 94 cases: of these, in 13 both heads presented; in 9 the head and breech or inferior extremities; in 2 one presented with the head, the other transversely; in 1 both with the breech or inferior extremities; and in 1 the breech and shoulder. In 7 of these cases the children were both boys; in 8 both girls; and in 11 of different sexes.

* In p. 152, line 4, for lbs. read pints; line 10, for an, read our; line 12, for chlorinic, read chlorine; p. 153, line 27, for gra. read oss.

1285 were males.

1188 were females.

2408 were presentations of some part of the head, of which 17 were face presentations—about 1 in every 145½ births; and 3 were presentations of the ear—about 1 in every 824 births.

57 were presentations of the breech, or some part of the lower extremities—about 1 in every 43½ births. Of these 12 were twins.

8 were transverse presentations—about 1 in every 309 births. 3 of these were the second of twins; 2 were expelled by “the spontaneous evolution,” or rather doubled, between six and seven months, putrid; in 1 case the uterus ruptured itself. Only one of these children was born alive.

In 1 the placenta was implanted over the os uteri; the child was delivered by “turning;” it was dead; the woman recovered.

5 were complicated with alarming accidental hæmorrhage, not the consequence of placental presentation—1 in about every 489½ cases; 2 were premature. In all these cases the women were delivered naturally, the hæmorrhage ceasing, or being much diminished, after the membranes were ruptured; but in one the uterus relaxed after the expulsion of the placenta, and the woman died in less than an hour. Only one of these children was born alive, and that was premature.

In 10 the placenta was retained within the uterus, either by atony or irregular contraction of the uterine fibres, or by morbid adhesion between the uterine and placental surfaces, requiring the introduction of the hand for its removal—about 1 in every 245 cases. All the women did well; with all there was considerable hæmorrhage.

6 were complicated with alarming hæmorrhage, after the natural expulsion of the placenta—about 1 in every 412 cases. One of these women died immediately after a very rapid labour, before the midwife could arrive; another, who had been ill with fever during the latter part of her pregnancy, was delivered of a dead child; she seemed to be going on well till the eighth day, when she was suddenly seized with a violent attack of hæmorrhage, and never rallied.

4 were delivered by the forceps—1 in every 618½ cases. In one case, where the long forceps was used, the woman

had a narrow pelvis at the brim. All the children were extracted alive, and all the women did well.

2 were complicated with puerperal convulsions—one in every 1236½ cases. In one case the attack occurred a month before delivery; the woman had a succession of fits rapidly; she was relieved by bleeding and purging; the child was born alive, and she did well. The other happened to the patient for whom I induced premature labour in January 1832, in consequence of a malignant tumor situated on the right buttock, which was afterwards removed in the London Hospital, as stated in a previous report. She had enjoyed tolerably good health since, but had very recently become a widow. Soon after her labour she complained of pain in the head, which did not give way to the means employed. On the ninth day she was attacked with violent convulsions; bleeding and purging put a stop to the more alarming symptoms; but a state of coma, drowsiness, and semi-consciousness, continued, and, in spite of all the efforts used, she died in ten days from the commencement of the fits. An inspection could not be obtained.

In 2, premature labour was induced in consequence of a contracted pelvis—one in every 1236½ cases. In one of these the ergot alone was used; the head, funis, and hand, presented, and the child was born dead. In the other case the membranes were punctured, and this child also was born dead. Both women recovered perfectly.

10 women died within the puerperal month—about one in every 245 cases. Seven only of these, however, could be considered the consequence of labour, for two died of epidemic cholera, and one of dropsy—being one in about every 349½ cases.

2408 children were born living.

79 were born still, being about one in every 31½ births.

Of the Deaths—

3 occurred from hæmorrhage; one immediately after labour, before the midwife arrived; one in an hour after the expulsion of the placenta—there had been flooding before the birth; and one on the eighth day after delivery, of a sudden and copious gush of blood.

1 from convulsions on the nineteenth day after delivery.

1 the day after delivery under a shoulder presentation; the uterus ruptured itself by the violence of its action.

1 from hysteritis on the 8th day after delivery, the labour having been lingering.

1 at the end of the third week, from diarrhœa; this was owing to her own imprudence in regard to exposure and diet: at the end of a week from delivery she was well, and began to occupy herself in her domestic duties.

2 from Asiatic cholera—one woman died six hours after labour, having been the subject of the disease only 18 hours. Her death occurred on a Thursday, about the middle of September: on the Monday before, her husband was seized with the complaint, and died the next day; his corpse was in the same room with her when she was delivered; the infant died on the Friday, and another of her children on the Saturday following her death. The other woman died on the 8th day after labour.

1 from universal dropsy a few days after delivery.

Of the Still-born children—

32 were premature.

4 were putrid at full time or nearly so.

14 were breech presentations at full time or nearly so.

7 were transverse presentations.

1 was under a placental presentation.

4 were under accidental hæmorrhage.

1 was after a serious accident had happened to the mother.

2 were under premature labour voluntarily induced; with one of these the funis prolapsed.

With 4 the funis prolapsed by the side of the head at full time.

1 was an acephalous fœtus.

9 were at full time, the head presenting, not putrid, nor delivered by art; some of these were lingering labours, and one unusually so.

[To be continued.]

RECORD OF CASES.

By THOMAS MAYO, M.D. F.R.S.
Physician to the Infirmary of St. Marylebone.

(For the Medical Gazette.)

[Continued from p. 147.]

Pseudo-Rubeola.

THE supposition that measles sometimes occur more than once to the same person, perhaps owes its existence to the

occasional occurrence of a rubeoloid exanthema, mistaken for measles.

It is no doubt expedient that this mistake should be avoided, but besides this reason for paying some attention to pseudo-rubeola, it is probable that it has a character of its own, and a bearing upon disease, which it is inexpedient to neglect. Though such eruptions may not be measles, they will often be found in company with severe disorders of other kinds, and possibly may indicate the procedure by which the cure of the concomitant disorder may be effected.

In two remarkable cases at the Middlesex Hospital, I witnessed a concomitancy, or rather a sequence, of this kind. In each, after two days of pyrexia, rubeola apparently developed itself very fully, but without coryza. In both, after lasting about 36 hours, it abruptly disappeared. Small vesicles were then observed extensively grouped, and these turned out to be a varioloid eruption, which in each case ran its course very fully; the patients being young, and having on their arms the evidence of vaccination. In the second of these cases, I witnessed, on careful inspection, the small vesicles apparent, before the rubeolous eruption had disappeared.

On the 1st of October, 1841, Stephen Lloyd, a fine, well-grown boy, aged 3 years, came into the Marylebone Infirmary with some feverish symptoms. On the 2nd, measles came out, and ran a mild course, in regard to which I have only noted that there was less than the usual coryza. A powder of rhubarb gr. viij., calomel gr. j., was given at first, and the mistura antimonalis was continued throughout it.

12th.—Pertussis now occurred, unmarked by any symptoms of severity. It was treated with the Pil. Saponis c. Opio, in small doses, the Pulv. Conii Co. gr. iv.* bisquotidie, and mild aperients.

16th.—The pulse being to-day rather sharp, Hyd. Chlorid. gr. j., Pulv. antimonal. gr. iij. was ordered o. n. and continued to the 23d.

21st.—The pulse was softened; but ronchus and deficient vesicular penetration were observed by me, posteriorly,

on the lower lobes of the right lung; and this state continued nearly unaltered through the whole case.

Applicatur Hirud. iij.; Sumantur Mistura Tragacanth. ʒij.; Vin. Ipecac. ℥v. 6tis.

23d.—Hydrarg. Chlorid. gr. ss.; Pulv. Ipecac. Co. gr. ij. 8vis.

24th.—Repetantur Hirudines iv.

The above powders were discontinued, as they dried the tongue.

Mistura Antimon. ʒij. 6tis.

This mixture was continued, more or less in quantity, to the end of the case, so as to produce frequent vomiting.

28th.—Repetantur Hirudines et post Hirud. applicetur Emp. Lyttæ, iuter scapulas.

30th.—Hydrarg. Chlorid. gr. ij.; Fol. Conii, gr. j. 8vis.,

to November 3d, when, strange to say, in one so young, salivation occurred.

On the above applications of leeches, the patient bled freely, always with marked relief of dyspnœa, which existed in no very high degree. The sputa, for throughout he spat freely, were not tenacious; they were muco-purulent, mixed with a little blood. The bowels were kept gently open by Oleum Ricini.

31st.—He was this day much better. Sputa to-day not streaked; more respiratory murmur in the affected portion of lung, but some gurgling. This improvement had, indeed, commenced with the salivation. It was observable that the heat of the posterior surface of the thorax, which had been disagreeably pungent to the touch, had much diminished.

Nov. 2.—The improvement had continued up to to-day; but he coughs much, though he rarely whoops. To-day he looks distressed, and dyspnœa has returned. Let him take enough Mist. Antimonial. to vomit him. The salivation is still existent, though less.

3d.—*This day an eruption of a rubeolous character has returned over his arms and chest; it lasted twenty-four hours. His breathing is noisy; streaks of blood again in the sputa.*

Emplast. Lyttæ Epigastrio.

Up to the 7th, he continued much the same. The bowels were kept open by Ol. Ricini; and Morphine Muriat. gr. ʒ, was given with some slight relief of dyspnœa, bis quotidie, for two days.

* Fol. Conii; gr. j., Pulv. antimonal. gr. j. Sodæ Sesquicarbon. gr. ij.

On the night of the 7th his teeth grated much; and through the 8th very little urine passed. He no longer noticed or answered questions; disposition to orthopnea; sputa easy, no blood in them. He screams much; his hands are contracted, and thumbs bent into the palms. These symptoms of cerebral disturbance continuing, he died on the morning of the 10th. From the 2d of November, until the head symptoms presented themselves, that is, up to the 7th, very strong flushes took place on his forehead and cheeks.

The stethoscopic phenomena of this case were observed by me only so far as I wanted immediate indications of practice, from my unwillingness to disturb the little patient.

Post-mortem examination. — Brain and membranes in a normal state, or slightly injected. Left lung normal, except that there were some miliary or granular deposits in the upper part. Right lung remarkable in being divided more vertically than usual, and into two lobes, which adhered throughout. In the middle and lower portion of that lung, a large mass of tubercle, very partially softened; posteriorly, one small cavity containing pus; the substance of the lung around the tubercular mass engorged. Mesenteric glands tuberculated, and much enlarged. The head symptoms in this case were plainly of thoracic origin.

Emma Shuttleworth, aged 4 years, came into the Infirmary, Nov. 10, 1841, with enlarged submaxillary glands. On the 12th, an eruption, having all the characteristics of measles, coryza included, took place, but lasted only twenty-four hours, though endeavours were made by sinapisms to recal it. Her convalescence was only marked by fretfulness; there was neither cough nor dyspnea: but on the 23d my attention was called to her by her feverish appearance, and my being informed that she would take no food. Her skin was hot; belly flatulently distended and tender; tongue smooth down the middle, and dryish; bowels open; urine sufficient; pulse quick. From this point of time to the termination of her illness, the thorax being often examined gave no morbid appearance, except some resonance of voice, and occasionally imperfect vesicular penetration, which at other times was not

noticed. Her fretfulness, combined with the above symptoms, drew my attention at this time to the abdomen; for there was no comatose tendency, no screaming, no complaint of head when questioned. About two days before her death, which occurred on the 28th, she was observed to grind her teeth; her cheeks were strongly flushed, and her tongue had become thickly coated. The evacuations at the last were green and loose.

Before the 23d, when pyrexia and tenderness of the abdomen engaged my attention, I had given some doses of Hydrarg. c. Cretâ with Dover's powder, with Mistura Cretæ Co. for looseness of bowels. On the 23d, two leeches, and afterwards an emplast. lyttæ, were applied to the abdomen, which materially lessened its tenderness and tenseness, but left pyrexia and quick short breathing unabated. The remainder of the treatment was Hyd. Chlorid. gr. j. bis vel ter quotidie. I suspect that very little food was taken by this patient throughout her illness. She was, so said the nurse, extremely obstinate.

Post-mortem, 24 hours after death.

Abdomen. — No other morbid point, than flatulent distension, some enlargement, not of an inflammatory character, of mesenteric glands, and some softening and enlargement of kidneys.

Thorax. — Slight engorgement of lungs partially observable.

Head. — Fluid effused between arachnoid and pia mater. The latter membranes very highly injected with blood, in some parts amounting to ecchymosis. Brain firm, and exhibiting many bloody points; more than the normal quantity of fluid in ventricles.

The common feature in the above four cases is the imperfect rubeculous eruption occurring in each of them, and in the third case exhibiting itself more than twenty days after the termination of normal rubella. In two of these cases the morbid action, of which the rubeculous eruption formed a part, was fatal. In the other two the occurrence of varioloid disease seemed, if I may speak hypothetically, to give the system adequate relief, and the patients did well.

[To be continued.]

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

Caloric; its Mechanical, Chemical, and Vital Agencies in the Phenomena of Nature. By SAMUEL L. METCALFE, M.D. of Pennsylvania University. 2 vols. pp. xix. and 1100. Pickering.

WE beg to refer to a late number for a sort of Lloyd's-list classification of books, in order that our readers may appreciate to the full the high estimate we are disposed to put upon the work the title of which is given above. It is at once an original composition, and a most comprehensive and enlightened review of the opinions that have been entertained, in ancient and modern times, on many of the most interesting and momentous problems of general physics and animal physiology. It bears the unquestionable stamp of genius, and carries with it, at the same time, evidence of learning various and extensive, and of such laborious research as can only be successfully achieved by minds of the noblest order in pursuit of sacred truth. And truly, we make bold to say, that we have never met with an effort so sustained, and, we add with confidence, so successfully made, to raise the veil from the shrouded statue of the goddess. The attendant priests of old would have trembled lest the face was about to be uncovered wholly, and would probably have called the sacrilegious hand of the author of this work. We live in happier times, and if Sais were now, and we at Sais, we know that we should meet the encouraging smile of the divinity, and not death, for venturing, with all reverence, to lift a corner of her veil.

So much by way of showing to our readers the general impression which the perusal of this excellent book of Dr. Metcalfe has made upon our mind. Let us take a brief survey of some of the matters treated of in its pages. The work is divided into two volumes, the division naturally indicated by the two orders of phenomena discussed, viz. physical and vital phenomena, and we shall follow the same order in our notice of the book, restricting ourselves, at this time, to the first volume, but

promising to ourselves the pleasure of returning to the second volume at an early date.

To the general reader the title of this book will hold out little that is attractive; the natural philosopher and chemist, however, are aware that the subject of caloric is one that is altogether paramount, and that discussing it in its varied agencies, we are, in fact, passing in review the entire domain of nature and of art. The subject, therefore, is one of intense interest in itself. The masterly manner in which it is handled by Dr. Metcalfe invests it with a kind of ideal attractiveness; and as we have but just discovered that history, to be true and improving, may be very different from the barren chronicle of events in which our forefathers believed its essence to consist, so have we here an instance of the delightful manner in which science may have letters and antiquities, poetry and philosophy, brought to her aid, and how, instead of having her presented to us as a lifeless skeleton, hideous in its nakedness, we may have a form instinct with life and motion, and clothed in loveliness, to look upon.

Despite of the vast importance which, by common consent, is ascribed to heat in the phenomena of the universe, the science of caloric was yet to create. What was estimated as this science consisted of a comparatively small number of unconnected facts, which scarcely found their application beyond the confines of the laboratory; it was left for the gifted mind whose work lies open before us, to make an extensive generalization of all the facts and phenomena known, and to demonstrate caloric as the prime mover in the universe—as the agent employed by God alike to convert into vapour, and to move in space the drop of dew, and to roll the planets in their orbits millions, billions of miles, from the source of power, recipients of life and conscious enjoyment from his hand. And then the whole piecemeal superstructure of preceding philosophers wanted the essential circumstance of substantial foundation. Up to the present moment it has still been a question whether caloric be an exceedingly subtle and active essence, as maintained by all the enlightened nations of antiquity, or consists in mere motion or vibration among the particles of

ponderable matter, as supposed by many of the most distinguished philosophers of modern times. Dr. Metcalfe, perceiving the necessity of settling this question, and of making the nature of caloric the cardinal point of his inquiries, sets out by showing that it is a material agent, and consists not by any means in mere motion or vibration among the particles of ponderable matter.—It may be added to, and subtracted from, other bodies, and even measured with mathematical precision by the thermometer. It augments the volume of bodies, which are again reduced in size by its abstraction. It modifies to infinity the forms, properties, and states of all other bodies. It passes through the most perfect vacuum that can be made, still producing all its characteristic effects upon the thermometer, &c. It exerts mechanical and chemical forces that seem irresistible—as in the eruptions of volcanos, the explosion of gunpowder, &c. It affects the nervous system in a perfectly determinate way; grateful in moderation, it produces intense pain and disorganization of the animal tissues in excess. “But,” says our author, “if caloric were a mere property or quality, how could it be taken from one body and added to another? And if it augment the volume of other bodies, must it not itself have volume, occupy space, and therefore be material?” We will own that to us it does seem absurd to stake the material existence of anything upon the mere possession of appreciable ponderability; volume and condition are surely as good tests of entity of material existence as weight. Wherefore should we then say that that which, added in the quantity indicated by 980 degrees of our ordinary thermometric scale to a *cubic inch* of boiling water, converts it into a *cubic foot* of invisible vapour, or which, subtracted to a still greater amount from the vapour, turns it into a solid—a mass of ice—had not an actual, a material existence? To say that *motion* can have any such effects is absurd; for motion is obviously not an agent, a cause, but an effect, and implies a mover. Neither have we any difficulty in conceiving caloric as existing distinct from other bodies: it passes through the most complete vacuum of the air-pump that can be procured, undiminished in quantity, unaltered in

quality; and it traverses the vast, and, in regard to air, much more perfect vacua of planetary space, to impress life upon the orbs it encounters, in accordance with fixed laws which do not differ from those that have been assigned to gravitation—it diminishes inversely as the squares of the distance.

Our author's next object is to show that caloric is a self-active principle, which has not only the power of motion within itself, but that of giving motion to all other bodies. That the particles of caloric are idio-repulsive is universally admitted; that it has the faculty of engendering motion among the particles of all other matter, appears from every one of the phenomena with which we are most familiarly acquainted. Witness its effects upon the particles of water, now coherent and constituting a solid, now gliding easily over one another and forming a liquid, and next flying apart in the shape of an elastic vapour, which gains power with every additional degree of caloric until it upheaves continents and makes the solid crust of the globe to tremble. All changes and transformations of matter being immediate effects of motion among its particles, caloric the efficient cause of motion everywhere present, in the pores of bodies, as in the stellary spaces, what do we require more to conclude that caloric has all the attributes of a *vera causa*—the power of moving itself, and of generating motion in other bodies—that we have attained to a knowledge of the grand means which the Almighty has used in fashioning, and which he still uses in upholding, the fair fabric of the universe? In the total absence of caloric, the particles of ponderable matter would have no power either of attraction or repulsion, no power of motion—nature would then be truly dead; whence the conclusion that the activity or moving power of all bodies is directly in proportion to the quantity of caloric around their particles, and, by an extension of the same law, that all molecular motion, whether centrifugal or centripetal, is referrible to the property inherent in caloric of repelling its own particles, and of attracting the particles of ponderable matter with forces that vary inversely as the squares of the distance. Here, then, we have the physicist, or natural philosopher, upon a height such as he has never attained

before, and with a positive knowledge not only of the things acted on, but of the agents, calculating the reciprocal influence of the masses which compose the universe, with the same assurance that the chemist now calculates the combining proportions and affinities of the ultimate elements of matter.

We beg particularly to call the attention of our readers to those chapters in which our author demonstrates, as we think in a manner not to be gainsaid, that caloric is no less the cause of cohesion and chemical affinity than of repulsion and expansion. At the commencement of the Second Book he says:—"There is nothing more remarkable in the history of science, than that the phenomena of attraction should have been so far unfolded and generalized, without any definite knowledge as to its cause. It would seem that one of the first inquiries of the philosopher ought to be, what is the agent or cause of the force, by which the atoms of matter are held together? and that the most natural answer would be, that which surrounds and fills the spaces between them." But we have not space to follow the author in the clear and logical argument by which he has arrived at the following conclusions, which, nevertheless, we give entire:—

"1. That cohesion, chemical affinity, and capillary attraction, are modifications of that universal force by which planets and all other bodies are held together.

"2. That the particles of all bodies are surrounded by, and intimately combined with, an exceedingly subtle, active, and mobile principle, which in certain proportions holds them together, but in larger proportions separates or decomposes them.

"3. That the prevalent theory of physics which ascribes the phenomena of attraction to the inherent, or immaterial properties of ponderable matter, is fallacious, and wholly unsupported by evidence.

"4. That there is no such thing as a perfect *vacuum* in nature; neither in the pores of bodies, nor in those widely extended pores of the universe, termed the planetary spaces.

"5. That the *inertia* of matter is a philosophical fiction, because there is nothing quiescent in nature, or which

possesses the *power of not acting*—neither in the starry heavens, nor in the frame of the earth. The sun revolves on his axis, and planets around the sun. The air, the ocean, and the solid ground, are for ever in motion. The molecules of plants and animals are in a state of rapid circulation and change. Yea, the invisible atoms of inorganic matter are in a state of perpetual oscillation and transformation.

"6. That the 'unknown hypothetical æther' of Sir I. Newton is identical with a true physical agent, the properties of which may be ascertained by the various mechanical, chemical, and physiological effects it produces; that it causes the aggregation and chemical union of bodies, whether simple or compound, by virtue of its *attraction for ponderable matter, and not by pressure*, as supposed by Newton; while it causes evaporation, gasfaction, explosion, with all the separations and expansions of matter, by virtue of its *idiosyncratic repulsive power*. •

"7. That if the earth were wholly deprived of caloric, it would become a stupid mass of inert and chaotic matter, without form, and void of all power of attraction and repulsion, of solidity, fluidity, &c.

"8. That the total extinction of the solar fluid (if such a thing were possible), would mark the reign of everlasting stillness and death; that the same æthereal principle which lights up the universe with radiant glory, directs the planets through their orbits, and preserves them in a state of perpetual motion, circulation, and renovation. Finally, that caloric is the first of second causes."

All the meteorological, and most of the physical, phenomena that take place on the surface of our earth, are simply due to variations in the quantities, or in the effects, of the caloric that is ceaselessly emitted from the sun. "Were it not for the heating power of the sun," says our author, "there would be no contractions and expansions of the atmosphere, therefore no winds. But in the present order of things, not a single atom of the great aerial ocean is quiescent for a single moment of time.

* • Were the earth of uniform surface and elevation, there would be a gradual and even diminution of temperature from the equator to the poles, and the

winds would be as regular as the movements of the heavenly bodies. But owing to the present distribution of land and sea, mountains and valleys, plains and woods, the temperature of the globe is infinitely diversified even in the same latitudes. Were it possible, indeed, to compute the aggregate forces of caloric in all the mechanical, chemical, and vital transformations, which are for the most part unobserved, we should be astonished at the result; but men are so accustomed to the regular course of nature, that they are less aroused by the grandeur of the sun rising in pomp and might, filling the world with beautiful creations, and diffusing every where the spirit of gladness, than by a passing meteor of the night."

That the whole theory of geological dynamics is immediately connected with the agency of caloric, is now universally admitted; and the way in which our author has connected the science of geology with that of astronomy and general physics is exceedingly happy. In the mass of interest which the book contains, indeed, this is one of the most interesting parts. The great changes of climate which the earth has certainly undergone, and the numerous cycles of organic life it has supported in the lapse of the long geological epochs whose histories are written in the deeply cut and clearly legible characters brought to light by modern science, are all referred to gradual changes in the inclination of the earth's axis, which, by varying from 0°, when the plane of the equator would correspond with the plane of the ecliptic, to 30, 40, or more degrees, suffices to explain all antecedent phenomena as satisfactorily as the present inclination of the earth's axis, of 23° 28', enables us to account for all existing diversities of climate and of season. The obliquity of the earth's axis is admitted to be actually diminishing at the rate of one minute in 126½ years; and if it goes on decreasing in the same ratio, without interruption or retrogradation, neither of which can be supposed, it will totally vanish in the course of about 177,760 years, when there will be no more winter nor variations of seasons in any part of the earth, and a grand physical millennium will ensue: then, in the words of the poet,—

"Will the spring
Perpetual smile on earth with verdant flowers,
Equal in days and nights, except to those
Beyond the polar circles; to them day
Will unbenighted shine, while the low sun,
To recompense his distance in their sight,
Will round the horizon still, and nothing know
Of rising East or sinking West."

The time has long gone by in science, when mighty names are allowed to have any influence of the kind that checks inquiry. In medicine, we debate the physiological conclusions of Harvey, and Hunter, and Haller; and, without dreaming of offence, we repudiate what is false, amend what is defective, and add that which is new. In physics, again, Kepler and Newton are freely canvassed, and their strong points confirmed and extended; their weak points, as a matter of course, rejected. Newton's first law of motion, for instance, which has long been held as very questionable by the highest authorities, most ably criticised by our author, under the guidance of his own peculiar views, and of all that science has achieved since that great man lived. This law, announced in these words in the first book of the *Principia*,—"Every body perseveres in its state of rest or of motion, unless compelled to change that state by forces impressed thereon,"—is the foundation, as is well known, of Newton's theory of planetary motion, according to which he maintains that, when first created, the earth and heavenly bodies were projected into empty space by the agency of a primitive impulse, communicated at various distances from their centres of gravity, by which their annual and diurnal revolutions have been ever since maintained without any renewal of the cause. See how ably our author criticises these views.

"In all the operations of nature with which we are best acquainted, *force is always expended in producing motion; and if not as constantly renewed, is very soon exhausted.* Nor have we the slightest proof, that motion is ever generated without the immediate agency of some active principle. The power of steam is created by the immediate agency of caloric, and ceases whenever the acting principle is withdrawn. The force with which a horse-shoe magnet of soft iron holds on to the armature is generated by the passage of an electric current through the wires which are coiled around it; but ceases the

moment the current is arrested. The metallic wire that connects the extremities of a voltaic battery, attracts iron filings, and deflects a magnetic needle in its vicinity, so long as the electric fluid is disengaged by chemical action, but ceases whenever that action is at an end. The powers of digestion, secretion, nutrition, and muscular motion, are generated by means of an active principle which is obtained from the atmosphere by respiration; but cease whenever that important function is arrested.

"But if it be true that caloric is perpetually radiated from the sun and fixed stars into the boundless regions of space, it must constitute an infinite ocean of æthereal essence, and there can be no such thing as a vacuum, which, as Aristotle rightly observed, would destroy all motion. Nor is it less obvious, that if caloric be a self-active principle, and is every where present, there can be no such condition of matter as *vis inertia*, which literally means the power of not acting. And that a single impulse is not competent to maintain the unceasing motion of planets and satellites, is evident from Newton's own hypothesis, that they are impelled or *drawn* with an equal force at right angles to the direction of the original projection. Moreover, when Newton referred the centrifugal force to the immediate agency of the Deity, and that of gravity to an inherent property of matter, he departed from that uniformity of nature and of causation on which all true science is founded. To be consistent, he ought to have referred all physical power to the immediate agency of the Deity, or to the inherent properties of matter.

"But if the centrifugal force of planets," proceeds our author, "be directly in proportion to the radiating power of the solar orb, caloric must be the cause of this force; for one essential character of a true cause is, that the effects it produces are a measure of its intensity. Nor is it less certain, that if the caloric which is perpetually radiated from the sun be not annihilated, it must either accumulate in the planetary spaces, and thus raise their mean temperature; or it must return to the great fountain from which it emanates. It also follows, that if the vast æthereal tide flow perpetually towards the sun, with the same force

which it exerts in maintaining the centrifugal power of planets, there is no good reason why it should not be the cause of the centripetal force which maintains them in their orbits; consequently, that the projectile and gravitating forces of Sir Isaac Newton are owing to one and the same principle, which produces all the contractions and expansions, separations and combinations, of the particles of ponderable matter.

"Moreover, if it be true that there is an unceasing circulation of æthereal matter throughout the solar system, it will account for the revolution of the sun on his axis; a phenomenon which has never yet been explained in accordance with the Newtonian theory; and the knowledge of which is of fundamental importance to a right understanding of physical astronomy; as it is in the laws which regulate the actions of the sun, that we must seek for the origin of planetary motion."

Caloric, in short, is what Homer calls—

"The golden everlasting chain,
Whose strong embrace holds heaven, and earth,
and main."

Dr. Metcalfe has also devoted a considerable portion of his work to the obscure subject of electricity, which he maintains is only a modification of caloric; and we have no hesitation in saying that, to our mind, he has clearly demonstrated their mutual convertibility, — that caloric is lightning, lightning a concentrated form of caloric, which, having converted a large quantity of water into vapour, is given off in an explosive manner on the sudden condensation of the vapour by a mass or current of cold air. In those parts of the world where no rain falls, *i. e.* where there is no sudden condensation of transparent aqueous vapour, there is no thunder and lightning; it is most frequent, on the contrary, in those latitudes and localities where, and at those seasons when, there is the most copious precipitation of moisture in the shape of rain. If caloric is proved, beyond all question, to be the true and only cause or agent in evaporation, which it certainly is, it becomes self-evident that the condensation and precipitation of the moisture can only be effected by the abstraction of this agent. Within the tropics, during the rainy season,

the first indication of an approaching storm is known generally to be a light wind, with a few scudding clouds; it begins to lighten, and the sky is immediately obscured by dense clouds, that forthwith descend in torrents of rain. It is the transparent or elastic aqueous vapour, therefore, that is the vehicle of the electricity—of the caloric, —not the masses of condensed moisture constituting clouds, as is commonly supposed. Lightning has occasionally been observed to dart from the clear sky, and the occurrence has been held one of those portents of which ignorant man is so observant. De Luc has described the phenomena attending so remarkable an incident which he observed. "The storm commenced with abundant discharges of electricity from," as he says, "*dry transparent air*, and clouds were formed around the summit of the Buë upon each explosion." Whence came the clouds, if the air was dry? The air, however, was charged with transparent aqueous vapour, which, being suddenly condensed, gave off its caloric in the concentrated form of lightning, and immediately fell as a cloud, or as rain. The author, along with several other persons, had an opportunity of witnessing the same phenomenon as De Luc has described on the 2d of June, 1833, at New York, about 7 p.m., after a showery day. "The wind was from the south, while the western sky was of a brassy hue, through which the descending sun was perfectly visible. In this state of the atmosphere, a vivid streak of lightning was seen to dart from it, when clouds were immediately formed that intercepted the solar rays, as if an immense black curtain had been drawn across the western sky, and attended with copious precipitations of rain. Several showers were thus produced by successive flashes of lightning; and during their intermissions the sky became partially transparent, but of a brassy hue as at first.

"Such facts afford more decisive information in regard to the nature of lightning, than volumes of mere speculation, or than thousands of artificial experiments; for they completely establish the important fact that elastic vapour, and not clouds, is the proximate source of atmospheric electricity."

We have, ourself, at the Polytechnic Institution, seen electric sparks, flashes

of lightning, concentrated caloric, in stream half a yard in length, drawn from the steam pipes of a boiler, these electric sparks, or flashes of lightning, having been infused into the elastic vapour of the boiler by a coke fire beneath it. —But our space warns us to desist, at this time, from the interesting labour we have in hand; for next to the glory of having written an original and important work, is the pleasure which is experienced in perusing and analysing it. Dr. Metcalfe has undoubtedly achieved the glory; we have had the pleasure. In a second notice we shall shew how learning, linked with genius, handles the subject of life and organization.

MEDICAL GAZETTE.

Friday, May 17, 1844.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."
CICERO.

PRESENT STATE AND FUTURE PROSPECTS OF THE MEDICAL PROFESSION.

"It is said that among the policemen on the Great Western Railway, are eight members of the Royal College of Surgeons, and three solicitors."—*Globe*; transferred to *Times* of Friday, May 10.

We beg to call the serious attention to these words, of parents and guardians who may be contemplating the education of their sons and youthful charges to the medical profession. In the doubt and difficulty in which they are placed with regard to the disposal of the rising generation, let them pause before they thrust them upon a line of life in which the chance of success is becoming every day more and more largely mixed with the likelihood of failure, in which success itself is already a matter of comparative negation, for success now but barely enables a man to live, and scarcely permits him to cherish the hope of educating his family and sending them abroad into the world in advance of

his own station in society, which is always a point of honourable ambition with every mind of the better order. And let it not be said that these members of the Royal College of Surgeons and certificated solicitors were indifferent characters, *mauvais sujets*, men who broke down through inattention, or dissipation, or misconduct. The office of policeman upon a railway admits of no such unworthy subject as its representative. Policemen on railways are uniformly men of good conduct, and of sober habits. The sole explanation of the presence of these men in such a situation is to be found in the fact of their inability to exist by the profession in which their friends had placed them; and this by reason of no fault of theirs, but simply because of its overcrowded ranks. Men of education and intelligence are particularly in request upon railways; and as they are to be had upon the same terms as unlettered ignorance, they are, of course, greatly preferred by the directors, and do indeed make excellent servants.

WHY DO WE LIVE ISOLATEDLY AND ESTRANGED FROM ONE ANOTHER ?

"M. GAY-LUSSAC was present, for the first time, at the meeting of the Academy, since the occurrence of his accident, and thanked the members for the interest they had shown upon the occasion.

"The President expressed to M. Gay-Lussac the great pleasure which his restoration to health afforded to all his colleagues."

These pleasant words commence a recent number of the *Comptes Rendus*, or Account of Proceedings of the Academy of Sciences of Paris, and they give us a lively picture of the interest which men of science, in France, take in one another. There is nothing more gratifying to the sick man, when he is once enabled to shew himself abroad again, than to find a welcome to the

sun and air from his friends—from a single friend, casually encountered. How much more gratifying must it be to be welcomed by his associates in a body; to be bidden joy of his recovery by all at once whom he prizes most; to feel, from their eagerness to press his hand, that he was really dear to them, and that, had he died, he would in truth have had mourners among his fellows, who knew him best !

In England, and in London especially, we live too isolatedly, too much apart from one another; we fall sick, and we die and are buried, and not a soul, of all who knew us most intimately abroad, is aware of the circumstance till he meets us in the minion type of the Times newspaper, or—but this only in case we happen to have had some one who was peculiarly interested in us at home, and who watched the lamp as it faded, and flickered, and went out—till a card with a black border returns him thanks for the kind inquiries which he would have made had he known a syllable of our illness, but which, knowing nothing about it, he never made, and now feels sorry he had no opportunity of making.

It is a pity that *we* of the medical profession know so little, see so little of one another, that we have so little of truly legitimate and social intercourse. We are the comforters of all else who are in trouble and affliction, but we live without sympathy with one another; and if not in hostility, at least in the metropolis, for we rarely quarrel outright in London—it is only in Edinburgh that the doctors cut each other's throats—yet in indifference. Whence is this? We believe it is because we have no proper head, no rallying point, no centre where we can meet *en masse* on a footing of equality. Our societies do not supply the deficiency. In these there is too much of jostling and debate, too much of purpose to stand preemi-

nent, to shine, making perchance a foil of a brother to set off our own clear water. It is, therefore, with sincere pleasure that we see the recently-elected President of the College of Physicians, Dr. Paris, opening his house and holding out the hand of friendship and of fellowship to his brethren in such wise as makes us see this distinguished man even doubly worthy of the honour that has been conferred upon him. At such assemblies as those of which the President of the College of Physicians held one on Saturday evening last, we do indeed meet on a footing of freedom and of intimacy that is delightful; and there too we find an opportunity not only of knowing all that is most distinguished in our own profession, but of making the acquaintance of Right Reverend Prelates, and of Noblemen and Gentlemen known for their love of science and of letters; men who are pleased to associate with us, and with whom we in turn are pleased to associate. Such assemblies cannot fail to have the very best effect, not only by knitting the bonds of good understanding among ourselves, but of extending these bonds, and of linking us as representatives of our profession with those having political authority—a class from which we are too much estranged, whether it be for their sakes or our own. The only misfortune is, that as no private gentleman can hope to see all the profession at his house, the good effects of such meetings are necessarily limited. Dr. Paris, however, is not the only distinguished physician who receives his brethren in this pleasant way, and we trust that until we combine and get something of a Common Hall, or place of general meeting, which we ought to have, others of rank and influence in the profession will be found to follow up the good example he has set.

THE ROYAL COLLEGE OF SURGEONS.

It is said to be the purpose of the Council of the Royal College of Surgeons to give the most liberal interpretation to their lately received new charter; to raise to the rank of the fellowship all the members of a certain standing, who do not practise at once as surgeons, and trade as chemists and druggists; and to confer the same honour upon younger members, either on the recommendation of three of the present 300 select Fellows, or on their giving proof of their worthiness by undergoing the prescribed examination.

SYDENHAM SOCIETY.

THE Anniversary Meeting of the Members of this Society was held at the rooms of the Royal Medical and Chirurgical Society, on Wednesday, the 1st inst.: Sir James Clark, Bart. in the Chair. The report gave a very satisfactory account of the affairs of the Society, which now numbers upwards of 1700 members; and so well have the funds of the Society been managed, that the members of the past year will receive three handsome and valuable volumes—Hecker's Epidemics of the Middle Ages, Louis on Phthisis, and a new and admirable edition of Sydenham's Works, by the learned Dr. Greenhill, of Oxford. Dr. Paris was elected President, in the room of the late Sir H. Hallford; Dr. Babington, Treasurer; and Dr. J. R. Bennett, Secretary.

We cannot refuse ourselves the pleasure of adding a word recommendatory of this excellent Society, the objects of which are, indeed, of the best kind. Letters will not make the practitioner, it is true; but the practitioner is immensely aided and improved by letters. The Sydenham Society is the act of the profession to knit the bonds between learning and experience, between experience and learning; its want had been long felt by many of the better heads among us; and we confidently anticipate that, considerable as the number of members already is, it is destined to be tripled, or quadrupled, before the Society has reached its limits. The works in preparation for the present year's issue are the following:—Schwann's celebrated Essay on the Microscopic Identity of Structure of Plants and Animals, Hassé's Morbid Anatomy of the Thoracic Viscera, Hewson's Works, and the Works of Paulus Ægineta.

MEDICAL PROTECTION ASSEMBLY.

REMARKS ON THEIR ADDRESS.

To the Editor of the Medical Gazette.

SIR,

PERMIT me as an old surgeon—one of your earliest subscribers—to make a few remarks on "An Address from the Medical Protection Assembly," published in your last GAZETTE. Instead of viewing that production as calculated to "command attention" or "secure respect," I consider it mere bombast—an ebullition of faction. Besides, it bears falsehood on its front, in assuming to emanate from "the Members of the College," of whom, I imagine, only a comparatively insignificant number know anything about the matter.

The agitators are a sort of universal-suffrage men: they breathe not a word in relation to character, attainments, or experience, as essentials for the fellowship—a distinction that would be rendered worse than valueless by indiscriminate admissions. For who that possesses gentlemanly feeling would like to be associated with persons whose diplomas have not raised them above shop-keepers, or the vulgar practice of enticement by coloured bottles?

They talk of *emfranchisement*—a captivating word! but where is their thralldom? They have obtained, by a trifling payment of twenty guineas, the rights of members of the College, in access to its lectures, its magnificent museum and library;—recognition as surgeons, qualifications for lucrative appointments, and a passport to all the real advantages of the profession!

With these I have been ever satisfied. The shelter of my own vine and fig-tree, as the result of legitimate application, is somewhat better than the "protection" of the new associations, with which nine-tenths of English surgeons have no sympathy.

I am enabled to make this assertion by free intercourse with my professional brethren spread over a hundred square miles, of whom a large majority repose unlimited confidence in the discretion of the Council, and encourage no morbid desire for the new honour, independently of well-known and appreciated merit.

If the excited authors of the "Address" have cooled down sufficiently for sober reading, I recommend them to peruse the recently published life of Lord St. Vincent—it is excellent on points of discipline. I will quote a passage:—

"The shipwrights sent up to the Admiralty a set of delegates, who were expected to extort from the Board a compliance with several exorbitant demands. These gentlemen delegates were thunderstruck on being

informed that the Board had ordered they should be turned out of the Admiralty yard into the street!"—I am, sir,

Your obedient servant,
A LOVER OF ORDER.

May 4, 1844.

[Many men, many minds! *Licet omnibus*, &c. as we say by way of motto; and, therefore, we publish the letter of our old surgeon and friend. We have said our brief say on the "Address," and stick to it. If these same shipwrights made exorbitant demands of their superiors, their superiors served them right by turning them into the street. But when one party of gentlemen respectfully address another party of gentlemen, their equals, in so far as we have opportunity of judging from their tone and language, and rather admonishing them of their power to grant, than entreating them for certain concessions, we think there is always grace and breeding shown in listening, often both wisdom and justice displayed in yielding to the prayer of the petition.—ED. GAZ.]

UTILITY OF OPERATIONS IN THE CANCEROUS DIATHESIS.

AT the meeting of the Royal Academy of Sciences of the 18th ultimo, Leroy d'Etoilles read a memoir upon this subject. The most important element, in the surgical question, says the author, is to know whether or not it be true, that the disease, local at first, degenerates into a constitutional affection, and to ascertain whether the removal of the cancerous mass at an early period hinders this degeneration. The belief that these questions ought to be answered in the affirmative, and which influences surgeons in their practice through the early period of their professional life, would not, however, appear to be borne out by facts. Thus, M. Leroy has found that among 801 operations 117 had been performed within a year from the first appearance of the symptoms. Of the 117, however, there were already at the date of writing 61 in a state of relapse. But as 112 of the 801 operations had been done less than a year, it is certain that the number of relapses is more considerable now.

The results of operations for cancers of the lip are curious, from the differences they exhibit in regard to the two sexes. Of 633 men affected with cancer, there were 165 cases in which the disease was situated in the lip. 114 of them were removed with the knife, 12 with caustics; there were 15 ascertained relapses, or about one eighth. Of 2148 women affected with cancer, again, there were no more than 34 in which the lip was the seat of the disease; 22 became subjects of operation; 7 relapsed, or about one third.

There is no such difference of result in reference to cancer of the tongue; the disease is equally fatal in both sexes. Of nine operations in which the tongue was extirpated on account of cancer, three were done within a year of the commencement of the disease, and they recovered. The six others died with recurrence of the disease.

With regard to tumors of the breast, of 277 operations 73 were performed within the last two years, and the issue of these cannot yet be known. Of the 204 which remain, 22 had died within a year of the operation, and 87 had relapsed; more than one-half, consequently, had either been, or were about to become, the victims of the disease. In 27 of the cases the operation had been performed in the course of the year from the first appearance of the disease.

On the whole, M. Leroy believes that the following conclusions may be fairly drawn:—

1st, That the operation does not arrest the course of cancerous disease.

2d, The operation ought not to be had recourse to as a general means of treating cancer except in connection with the disease situated in the skin, or in the lips.

3d, The only plea for extirpating cancers in other organs is dangerous hæmorrhage occasioned by the progress of the ulcerative process.

MICROSCOPICAL AND PHYSIOLOGICAL RESEARCHES INTO THE NATURE, ETC. OF TUBERCLE.

BY DR. LEBERT.

THE constant microscopical elements of tubercle are: molecular granules, an interglobular hyaline substance, and certain corpuscles or globules peculiar to this abnormal product. The corpuscles are from the 0.005 to the 0.010 of a millimetre in diameter; their form is irregular, angular, the angles rounded; their contour is in general extremely distinct; they are yellowish, somewhat opaline, and contain in their contour a number of molecular granules, but no nucleus. Water, ether, and weak acids, scarcely alter them; concentrated acids, solution of ammonia, and of caustic potash, dissolve them. The yellow crude tubercle is the best subject for study. It is erroneous to suppose that tubercle is nothing more than a modification of pus; there are decided and distinct differences between the corpuscles of each substance, those of pus being larger, regularly spherical, containing one, two, or three nuclei, presenting a granular, or raspberry surface, and being free or isolated; whilst those of tubercle, especially in the crude state, are closely connected together. The globules of cancer are two or three times as large again as

those of tubercle, and contain a nucleus which frequently includes one, two, or three nucleoli.

The corpuscles of tubercle, when softening, absorb fluid, and become a little larger, and also become more segregated, but they still preserve their distinctive characters for a time; by and by they melt down into a granular fluid. Any pus globule that is met with among tubercular matter has proceeded from the surrounding parts, never from any transformation of the tubercle itself.

We often discover oil, melanotic matter, greenish-coloured fibres, globules, and crystals, having the form of those of the ammonio-magnesian phosphate, mingled with proper tubercular corpuscles and matter. When tubercles become cretaceous, we farther find amorphous mineral granules mixed with crystals of cholesterine and pigmentary elements.

Tubercles of the lung are usually seated in the elastic cellular intervascular tissue, but occasionally, also, in the cells, and even in the minute bronchi. The surrounding textures are mostly normal. The well-known grey semitransparent granulations of the lungs are tubercular; they do not always precede or prove the first step in the formation of the yellow miliary tubercle. These grey granulations are proved by the microscope to be no product of inflammatory action.

A tubercular cavern is a pulmonary ulcer, like any other ulcer. The fluid contents of these caverns are—*a.* tubercular matter, properly so called; *b.* pus globules; *c.* pyroid globules; *d.* granular globules; *e.* mucus; *f.* blood-discs; *g.* pulmonary fibres; *h.* pigment; *i.* epithelium; *k.* crystals; *l.* oil globules. Under the fluid we frequently find a true but incomplete pyogenic membrane.

The expectoration of phthisical patients comprises all the elements above enumerated, and even several others, such as little yellowish pellicles, remains of small membranes, certain vibrios, and the remains of food accidentally mixed with it.

Tubercles of the osseous system are rarer than is frequently believed; masses of concrete pus in bones are often taken for tubercular deposits.

Scrofulous diseases must be separated from tubercular affections, as also those chronic inflammations of the eyes, the glands, the skin, the bones, and joints, in which the most attentive examination brings to light no particular dysecrasia.

The grey granulations of the cerebral meninges contain the globules proper to tubercle; and the liver is often extensively affected with proper tubercle, which is sometimes confounded with cancer. The microscope enables us to distinguish between them.

The intestinal tuberculous ulcer does not produce pus; there is merely the debris of the mucous and muscular coats mingled with different tubercular corpuscles and cylinder epithelial scales, the young cells of which are apt to be mistaken for pus globules.

In a few very rare cases tubercular matter is discovered between the coats of arteries. The pericardium occasionally contains an abundance of tubercular matter in old false membranes.

Tubercle and cancer are not mutually exclusive; they are occasionally encountered together.—*Comptes Rendus*, No. 10, 1844.

GENERAL LAWS REGULATING THE DISPLACEMENT OF FRACTURES.

M. ED. LACROIX has published an interesting and philosophical paper on this subject, to which we beg to direct the particular attention of our surgical readers. His general conclusion is, that "*The displacements of bones occur in angles which have the same sines directed in the same planes and in the same sense as the natural curves of the bones implicated.*"

Clavicle.—Displacement variable according to the point broken; *forwards* when the two external thirds are broken off from the inner third; *backwards* when the two inner thirds are severed from the outer third; *upwards*, so as to form an angle with its apex superior, where the seat of fracture is the middle of the bone. When the clavicle is broken in two places, one towards the sternal, the other towards the acromial extremity, the natural curves of the bone are replaced by two angular knees, one of which corresponds to each of the solutions of continuity.

Humerus.—Displacement generally *outwards*, so as to form an angle the apex of which is external when the shaft of the bone is broken, not outwards and upwards as is commonly said by writers; the inferior portion of the bone is most apt to get in front of the superior. In fracture of the inferior extremity the displacement is mostly *forwards*, and there is generally an increase of concavity inwards, of convexity outwards; the inferior portion is also very apt to *rotate outwards and inwards*.

Forearm.—Tendency to displacement, *outwards and backwards*, when both bones give way in the middle. The ulna alone fractured in its upper portion, the tendency is to displacement *backwards and outwards*; in its lower portion to displacement *forwards and inwards*. The radius having given way singly in its upper third, the tendency to displacement is inwards, to the formation of an angle, the apex of which looks inwards; the bone having yielded in the middle, the

angle of displacement will regard *backwards*; and having failed in its lower third, the angle will turn *inwards and backwards*.

Femur.—Wherever seat of the fracture, the extremity of the superior portion of the bone tends to get *in front* of the inferior, and to form an angle projecting outwards.

Tibia.—When the bone is broken in its lower moiety, there is a general tendency to rotation, in which the inner malleolus becomes more anterior; and to the formation of an angle, the apex of which looks *backwards*.

Fibula.—Constant tendency to form an angle whose apex regards inwards, and more or less backwards.

Tibia and Fibula.—General tendency to the formation of an angle, with its apex turned posteriorly and internally. Less disposition to rotation than when either of the bones is broken singly.

But we must refer to the original and very ingenious paper of M. Lacroix for other and more particular information, in *Annales de la Chirurgie Française*, &c. Mars 1844.

THE NEAPOLITAN MEDICAL PRACTITIONER,

AND NEAPOLITAN MEDICINE.

DID the physician fail in the slightest of his duties as a thorough-going Roman Catholic, he would lose all credit, and would vainly hope for employment from the very lowest of the populace. From conviction, therefore, or necessity, he goes with the stream; he dares not oppose it in any way; he must not doubt of the efficacy of the sick man's devotions towards the recovery of his health, nor of the power of the amulets which the sound man wears in his bosom to preserve it. On the contrary, he must sometimes even recommend exorcisms and charms, as moral means at least. The principal ornament of the physician's consulting room at Naples is always a picture of the Madonna between two ornamented candlesticks. His first prescription in every case that keeps the patient in bed is to have a figure of the Virgin set upon a table covered in the fashion of an altar in the bed-room. The figure is bedecked with flowers and jewellery, and a lamp burns night and day before it. But the religious observance of the sick man does not stop here; however high his estimate of the celestial powers, it is by no means exclusive: as a good catholic he has a firm faith in the two principles, one good, the other evil, and he has no notion of imprudently committing himself to the protection of the first alone; he must likewise propitiate the second, and

take means to guard himself against its malevolent influences. It is this belief that has given rise to a prejudice or superstition known under the general title of *jettatura*, or evil eye. The devil does not act of himself so much as by proxy; these devil's proxies are *jettatori*, and it is enough to have a forbidding physiognomy to acquire the reputation of being one of that number. An enemy is of course always a *jettatore*. In front of such a conviction the Neapolitan has of course sought out some means of defence, and has happily found one which he holds to be of sovereign efficacy. It is extremely simple, and consists in carrying about with him a piece of coral, shell, or ivory, sculptured in the fashion of a horn; the shirt and breast-pins, the pendants from the bracelets, and the other little ornaments brought into play by Neapolitan coquetry, which have this fashion, are all of them so many amulets; and it is enough, having met a suspicious-looking person, to touch the amulet, to render his malevolent purposes null. To guard more effectually against *jettatura* or evil eye, the passage, lobby, or entrance-hall of the houses, have usually one or more pairs of these strange amulets upon a large scale, which perform the part of sentinel at the door. There is further safety in multiplying these horn-shaped amulets, so that they are frequently met with in every room of a respectable house; and the image of the blessed Virgin herself is sometimes flanked by a couple of them. The Virgin is a very good protectress, it is true; but the spirit of evil has too frequently got the upper hand in the world, to excuse any one for sleeping over securely, and relying too implicitly on her heavenly countenance.—*M. Carrère, in Gaz. Méd. de Paris, No. 13.*

[The above extract gives a curious picture not only of the state of medicine, but of a state of society which has long passed among us. A *horn* was often used as a symbol of sanctity among the ancients, as also of abundance—the horn of plenty. The head of Jupiter was sometimes crowned with horns—Jupiter Ammon, so was that of Bacchus, and all the world knows that Michael Angelo, not without warranty, has sculptured Moses in the same way. On one or other of the ancient zodiacs, instead of a *ram* as the sign of the vernal equinox, there is merely a pair of horns—a part was put for the whole.—The sun returns to the northern hemisphere in the sign of the ram, and with his return brings light and life; hence, say mythologists, the reverence in which the horn was held, is still held, as we see, among the Neapolitans.—*ED. GAZ.*]

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

List of Gentlemen admitted Members
May 10.—J. B. Barry.—M. H. Higginbottom.—R. T. Cobbold.—N. F. Hedley.—J. Fitzmaurice.—E. H. Edge.—A. Stansbury.—W. S. Walsh.—W. Leapingwell.—W. Brown.

NOTICE TO CORRESPONDENTS.

We have the excellent letter of "A.B.C.," and thank him for his suggestions, which he will perceive we shall by and by bring to bear upon the *enemy*.

Mr. Bird will have seen by this time that we differ from him entirely, and that it would be absurd in us to publish his letter, for which we nevertheless thank him. It is left at our printer's, or will be sent to his address should he desire it.

Guyensis' scheme is good. If he would make it *general*, not particular, we should take an opportunity of using it to advantage.

Medicus "On Medical Reform," is unavoidably postponed.

SUBSTANCE OF A CLINICAL LECTURE,
I.
ON INJURIES OF THE KIDNEYS.

II.
ON A CASE OF STRANGULATED
INGUINAL HERNIA.

Delivered at St. George's Hospital,

BY CÆSAR HAWKINS, Esq.
Surgeon to St. George's Hospital.

GEORGE FROGGATT, æt. 24, was admitted May 9th, at two o'clock in the afternoon. He was thrown off a horse this morning, and fell upon some railings on his left side, and afterwards upon the road. He could walk afterwards, but complains of pain on pressure at the lower part of the loins of the left side, and near the crest of the ilium, which parts are slightly bruised. No crepitus could be discovered. He says that he passed about a quarter of a pint of pure blood from the bladder about an hour after the accident, and has passed some blood in his water since his admission. There is no pain in the region of the bladder, and he has perfect motion of his legs. He has had pain in the loins some time before the accident, for which he has been under treatment. He has also slight cough.

5 P.M.—Pain much worse; pulse quick and strong; some sickness.

C. cruent. ad ʒviij.

Vespere.—Pain not relieved by being cupped; still passes some blood in the urine, and also a large quantity of lithate of ammonia. Leeches ordered.

On the next day, the 10th, the notes say, —Still more blood in the water, with a larger quantity of lithate of ammonia; bowels not open; pain lessened.

Calomel. gr. v. h.s.s. Sodæ Potassio
Tart. ʒvj. mane.

11th.—Was sick last night; bilious matter. More pain in the side, which was re-

lieved by chamomile poultice. Still much lithates; urine made transparent by heat; consequently without blood, or nearly so.

13th.—Less pain; but the urine is darker coloured from a little blood, but has less lithates. It is therefore transparent till heat is applied, when a little coagulum is thrown down.

Rep. Pil. et Haust. Sal.

14th.—Urine clear. [The urine has again contained some blood since the Lecture, but the man is going on well.—May 21st.]

Now here, gentlemen, I am inclined to think, from the nature of the injury, the sickness, the blood and lithates in the water, and the seat of the pain, is an instance of injury of the left kidney; and as I think this organ is injured more frequently than you might suppose from the little that is said about it in books, I propose first to-day to make some remarks upon such cases. I shall not allude to wounds of the kidney, of which some cases are to be found, but of which I know nothing, as I have not seen an instance myself. I had the curiosity yesterday afternoon to look through the indices of all the volumes of the two chief journals of the present day, the Medical Gazette and the Lancet, which profess to give very many reports, for the last twenty years and upwards, of cases of interest in the metropolitan and provincial hospitals, and of those abroad also; and yet, in upwards of eighty volumes, I only find reference to three cases: two of these are in the Medical Gazette, one of which is that of a patient of my own, and one is from the London Hospital; and the third case is reported in the Lancet, from St. Bartholomew's Hospital. Yet I believe I have seen a good many cases in which the kidney has been lacerated, or otherwise injured; but (which is one reason why so little is written on the subject) a great many persons who, I think, have experienced such an accident, have afterwards recovered, as even those have done who have had the

R

kidney directly wounded from without. Thus I only find in our post-mortem register, in the last three years, one fatal case recorded, which was in my accident week.

This was a man, Joseph Hunter, æt. 25, admitted August 8th, last year, in a perfect state of collapse, after a fall, I think, from a height, who died four hours after admission. There was no external appearance of injury, with the exception of the skin being discoloured over the right haunch. All the ribs of the right side were broken externally to their angles, the third, fifth, and seventh being again broken two or three inches posterior to their junction with their costal cartilages. There was considerable effusion of blood in the right pleura, and the middle lobe of the lung was lacerated. In the abdomen the liver was superficially lacerated all over. The right kidney was also considerably lacerated, with effusion of blood into the peritoneum, and round the kidney. The right ilium was fractured obliquely from the anterior superior spinous process to the posterior, and there was much effusion of blood under the fascia.

1. Such a complicated injury as this would necessarily prove fatal; and you see in it one mode in which laceration of the kidney may be fatal, namely, by hæmorrhage into the cavity of the peritoneum, with the addition probably, if the quantity of blood lost did not itself cause death, of the passage of some urine into the peritoneum, and its there producing its usual irritating effects.

Such laceration of this organ may occur from a fall, or a direct blow on the side, and is often accompanied by fracture of some of the lower ribs. It is, of course, more likely to take place if the kidney happen to contain a calculus, which will resist the blow from within, so that the structure is squeezed between two hard bodies. I remember a man being brought into the hospital under Mr. Keate, who thus, unfortunately, had calculi in both kidneys; and one of them being ruptured, with the peritoneum in contact with it, the patient died of the hæmorrhage. Whether our present patient has had a calculus dislodged by his fall, or the kidney torn, I cannot say; but you will observe that our notes mention his having been under treatment before the accident for pain in the loins.

2. Secondly, the substance of the kidney being lacerated, with its capsule, blood and urine may escape into the cellular tissue around it, without the serous membrane being torn; and the fatter the person is, the more distant the peritoneum will of course be from the gland. A great quantity of blood may here be effused, and cause death by its loss or by irritation; and the urine may add to this irritation, as it escapes from the lacerated part. It is curious that second-

dary hæmorrhage may thus be fatal some time after the patient has appeared to be going on well. There may be no blood, perhaps, in the urine, or it may have stopped, and on the third or fourth day after the injury there comes on sudden prostration, and pain and irritation, and the patient dies, and a great quantity of blood is found at the back of the abdomen, behind the peritoneum. I have seen this myself, both with laceration of the kidney and also of the spleen, in different cases,—the latest on the fifth day; but of the two cases, which I mentioned as being recorded in the journals besides my own, one was said to have been an instance of secondary bleeding as late as the tenth day. It was in a man taken to the London Hospital after a wall had fallen on him, who appeared to be going on well, only complaining of weakness, till ten days afterwards, when he was suddenly seized with great pain in the loins and prostration of strength, and the abdomen became distended, and he died eight or nine hours after this attack; and on examination, a great mass of blood was found behind the peritoneum, in the middle of which the kidney was found torn in half.

3. In the next place, there may be no laceration of the capsule of the kidney, but an injury may extend into the infundibula and pelvis of this gland, so that the effused blood escapes into the interior, and there is hæmaturia. The quantity that may be lost in this way is very great. A man, for instance, was brought to the hospital under my care, who had fallen from a coach-box, and probably had a fracture of part of the base of the skull. In the evening there came away with the water not less probably than three pints of blood; and a great quantity continued for the next three days, so that he was very near dying of the hæmorrhage; after which it gradually diminished, and he got well.

But you will naturally ask, how do I know that the blood came from the kidney at all? In most cases, perhaps, of hæmaturia, the blood is derived from the vessels of the bladder, and is very often witnessed when the pelvis is fractured; and it is curious that in many cases, where a good deal escapes, and you have no doubt of its being from the bladder, you can nevertheless scarcely find what has been its exact source. In our post-mortem register, for instance, is the case of a man, whom some gentlemen may remember, who was admitted in February last year, under Mr. Babington's care, and who had a good deal of blood in the urine. He had a fracture of the sacrum, and separation of the symphysis ili, and of the symphysis pubis; and in the bladder was a spot of ecchymosis: but it is noticed that there was no lesion of the mucous membrane,

though its vessels, in all probability, must have been injured to occasion the hæmorrhage. But there can be no doubt that in some cases of blood in the urine it is derived from rupture of vessels in the kidney, the injury being, however, not to any great extent. If a blow has been confined to the side, with or without fracture of the short ribs; if there has been no fall likely to have done mischief about the bladder (and the ureter is incapable of bleeding much), particularly if the blood is equally diffused in the water, or is moulded, as in this preparation, to the shape of the ureter, you can scarcely doubt that the kidney is the source of the blood. In our patient there is some pain and bruise down the whole side, making the case less certain, and the blood first passed is said by him to have been nearly pure, which it more frequently is when the bladder is injured; but this appearance is of course not at all inconsistent with a renal origin, if the bladder happens not to contain much water when the blood gets into it.

It is curious, however, that you will sometimes feel uncertain, even after death, when the injuries are somewhat complicated. A man was admitted under my care into the hospital, who had fallen from a scaffold about fifty feet, striking against the lower scaffold, and thence into the area. He was stunned for a short time, and remained in a state of collapse for some hours. He had several of his ribs broken on the left side, followed by inflammation of the lungs, of which he died twelve days afterwards. He had contusions in several parts, particularly in the right groin and pubes, and in the loins. He made water without difficulty or pain, but it contained a good deal of blood, giving it a dark colour, though without coagula: this began to diminish two days afterwards, but he had much pain in the left side and downwards towards the hip. The bladder seemed uninjured, with some coagula near it from separation of the pubes, the joint not being inflamed; and the left kidney, which I supposed was the source of the hæmorrhage during his life, was much more vascular than the other, but I could not find any rent in its substance. The lung was much inflamed.

A man was admitted into the hospital after having fallen sixty feet from a scaffold upon some timber, among which were a number of iron bolts, and he supposes he must have fallen upon one of them. There was a small wound behind the anterior superior spinous process of the ilium, to the bottom of which the finger could not reach, and the glutei muscles seemed much torn away from their origin. A small piece of the spinous process was broken off, and a larger piece was found to be cut, as by a sharp instrument, along the whole length of

the bone, but was not loose; and there was also a fracture of the ramus of the pubes close to the symphysis, with effused blood in both places. In this man, the bladder was the next day full, and required the use of the catheter; and on the second day the urine was mixed with a large quantity of blood; the third day it was again clear. This man was very restless and weak, particularly after the bleeding in the water: there was some delirium, as if from depression; and on the third day the urine and feces passed involuntarily, though the motion and sensation of the legs were perfect. He died on the third day, and, to shew the source of the hæmorrhage with the urine, I found a little effusion of blood in the texture of both kidneys, with slight hæmorrhage in the cellular tissue round them, but no direct laceration of either. If, then, the bleeding, as I believe it did, took place in these cases from the kidney, it is evident that an injury, accompanied by hæmaturia, may implicate the gland so little as not at all to interfere with the recovery of the patient; and therefore in most fatal cases we may expect some complication with injury of the chest, or of the pelvis, the latter of which leaves the source of the bleeding somewhat in doubt.

4. Your diagnosis in cases of injuries of the side will sometimes be assisted by your finding the secretion of urine altered; in our present patient, for instance, you have seen the water much loaded with lithate of ammonia. A man was under my care with fractured ribs after a blow, who felt great pain in the side, and had bloody urine, the blood being diffused through it without coagula, and on the third day the quantity of lithates mixed with the water was not less than a third in height in the vessel which you looked at; but in a week's time it was all right again. The deposit of the saline ingredients of the urine is quite disproportioned to the fever produced by the accident, which, in our patient, has been almost nothing, and such an alteration of secretion, with blood, and with pain in the side or loins, following a blow over the short ribs, or on the lower part of the back, may be considered, I think, tolerably decisive of there having been some bruise or laceration of the kidney.

5. In some cases of injury you will find a mixture of symptoms arising from injury of the bladder, or its nerves, or concussion of the spine, besides what appears to be some injury of the kidney. A man was under my care for a fracture of the leg, occasioned by a fall from a tree in the Park: at first, the bladder was paralysed, so that he required the catheter, the urine being healthy; then in a day or two there was deposited a great quantity of lithates, and shortly he had much irritation of the bladder, with

constant desire of passing it, though he remained incapable of expelling it: then he recovered some power over the bladder, and a large secretion of mucus took place from this organ, in consequence probably of the deposit of the lithates to such an extent, and in the course of a fortnight all these symptoms subsided. Another man was under my care many years ago, about the time of those remarkable crimes in Edinburgh, connected with our profession, which gave a new name to the catalogue; this man, a tailor, unfortunately dreamt that he was being Burked, as it was called, and, getting out of bed in his sleep, fell from the top to the bottom of the house through a skylight, which perhaps broke his fall so as to save his life. He had a fracture of the pubes, and of some ribs, and being unable to make water, I passed a catheter, and found only one table-spoonful of blood and very high-coloured urine; for the next twenty-four hours not a drop seemed to be secreted: after this time a very small quantity was found, exceedingly fetid, very acid, and with copious deposit of lithates, and with sulphuretted hydrogen enough to colour the catheter; and it was several days before the natural quantity and quality of the urine were restored. On the third day, the bladder recovered a little expulsive power, which then again ceased, and it was nearly six weeks before the bladder and the muscles of the legs, which were also partially paralysed, fully regained their power of contraction. The man finally recovered, and probably suffered from concussion of the spine, in consequence of which the functions of the kidneys were for a time suspended, as if their nerves were cut or injured in experiment.

6. A further consequence of injuries of the kidney seems to be suppuration within the organ, of which this case is an example. Charles Bradford, 24 years of age, was admitted under my care in October 1829, saying that a fortnight before he had fallen from a horse, and had had bloody urine two days afterwards, and at intervals since that time. Five days before his admission, an increase of pain took place, with fever, and pus came away in considerable quantity with the water. He had, on his admission, much tenderness on the right side, and constant pain referred to the right lumbar region, and there was much pus in the water. He had a full strong pulse, a loaded tongue, and anxious countenance, and he had previously had ascites, and had suffered from rheumatism, with disease of the heart. In the course of a month he went out nearly well, having previously had the irritation excited by the pus in the water propagated to the orifices of the vasa deferentia, so as to occasion hernia humoralis, and to the

urethra also, producing a purulent discharge from that membrane, as in gonorrhœa. He was again admitted at the end of November, with some return of pain in the loins, abdomen, and chest, and cough, and other symptoms of hypertrophy of the heart, of which he was very near dying, and finally left the hospital nearly well at the end of December, no longer feeling any pain in the situation of the kidney.

This is the only case in which I have seen suppuration follow an apparent injury of the kidney at this early period, but in many cases of abscess in this organ and around it, which I have had under my care, or have witnessed, some blow or strain has been experienced at some former time, and has been said to have given rise to the train of symptoms which ended in renal abscess. Of the two cases I just alluded to as being recorded in the journals, one contained in the *Lancet* is said to have been an abscess of the kidney, opened six months after an injury by Mr. Stanley; the termination of the case, however, is not mentioned. Chronic inflammation ending in abscess need not occupy our attention at present, as whatever may have been its origin, the treatment necessary for it does not differ from ordinary cases of disease of this organ.

7. There is yet one more effect of injuries of the kidney which I must mention in order to complete the subject. You will find, in the *MEDICAL GAZETTE* of Nov. 24th, of last year, an abstract of a paper by Mr. Stanley, giving an account of two cases of injury, in the first of which a boy was squeezed between the wheel of a cart and the curbstone, the consequence of which, besides suppuration about the pelvis, was the formation of a fluctuating tumor on one side of the abdomen, the urine passing naturally; about nine weeks afterwards it was punctured, and nearly three pints of clear yellow fluid evacuated; and again twice more at intervals of eleven and sixteen days. Three months after this four pints were let out, then only six ounces; and after this the boy got well, or at least not suffering from what swelling remained. In the fluid which was drawn off, urea and the other ordinary ingredients of urine were found on analysis.

In the other case, the patient, a woman, who was knocked down by, and pushed before the wheel of, a cart, died about ten weeks after the injury. Two or three pints of similar urinous fluid had been drawn off; and, on examination, a large cyst was found behind the peritoneum, and reaching from the diaphragm to the brim of the pelvis; and out of this sac a large irregular opening led into the pelvis of the kidney; and it was concluded that in this and in the former case a laceration of the pelvis of the kidney had been produced by the injury. In the

eighteenth volume of the Medico-Chirurgical Transactions I published an account of a case from which I took the preparation on the table before us, which I believed to have been an instance of aqueous encysted tumor of the kidney, similar to this transparent cyst of the kidney of another patient, which you see contained about half a pint of watery fluid. The boy, in this case, was admitted three weeks after he had been struck down by a carriage, and probably run over by it, with a considerable sized swelling on the right side of the abdomen, like an abscess in appearance, and occasioning much suffering. After a little while I let out eighteen ounces of water, with a little muco-extractive matter, but no albumen, and the boy died about three months after the injury, at which time the cyst filled the whole side of the abdomen, and contained about five pints of fluid. I say I published the case as one of serous or aqueous encysted tumor connected with the kidney: on looking at the preparation, however, there might be some doubt whether this was not an example of the same kind of laceration of the pelvis of the kidney which Mr. Stanley has described, as there were two small communications, about the size of pins' heads, between the sac and the pelvis of the gland; but it differs most materially from his cases in the nature of the fluid, which, instead of being urinous in smell, and being found to contain urea, albumen, and other ingredients of urine, was almost pure water. The case being a remarkable one, I ventured to request Dr. Prout to examine the fluid, whose authority is quite decisive on a question connected with the urine; and he was kind enough to say: "The fluid from the cyst is serous, and, after a careful examination, I have not succeeded in detecting any thing urinary in it; at least, if it contains urine, the quantity, I am satisfied, must be very minute." Now, that urine should escape into cellular tissue, and produce none of its usual inflammatory and sloughing processes, and collect in a large cyst in immediate contact with the peritoneum for several weeks or months, is, by itself, a very extraordinary circumstance; but that urine should thus escape, and form for itself a large bag, containing five pints of fluid, in which so experienced a chemist as Dr. Prout should detect nothing urinary, appears incredible; and I am inclined, therefore, to adhere to the opinion I then formed, of its being a serous tumor, such as becomes developed in other parts of the body, and that the minute communication with the pelvis of the kidney was formed by an attempt to empty the cyst in that direction by ulceration, rather than by laceration after the blow. You can see the thin cyst, with the ureter running within it, and with a small third kidney formed of one lobule at a

distance from the body of the gland. Still, however, it may possibly admit of doubt; and Mr. Stanley's description of his dissection seems to shew the possibility of an injury lacerating the pelvis or ureter.

It remains for me to speak of the treatment of injuries of the kidney. In the first place, with regard to the hæmaturia, it is seldom that its amount causes any alarm; but if the blood comes away in great quantities, you have the same resources as in other internal bleedings, to which alone you can look for checking hæmorrhage from the kidney which does not pass down with the urine. You can cause syncope by bleeding, and you can give styptics, which I have seen do much good in some cases of hæmaturia. Of these the best is lead; so that you can give three grains of the acetate with a quarter of a grain of opium every three or four hours for a time. In some cases, in which the lead failed, or alternately with it, I have seen the powdered galls stop the bleeding; this was the case in the man from whom this long coagulum of the shape of the ureter was withdrawn, who took fifteen or twenty grains every six or eight hours with much advantage. This medicine is, however, rather nauseous, and sometimes irritating to the stomach. You can also give a dessert spoonful of Ruspini's styptic every three or four hours. You might reasonably expect that, if these medicines have power in any case of hæmorrhage, they would be of especial service in hæmorrhage from the kidney, to which organ so large a quantity of blood is constantly passing. Another styptic — turpentine — which is useful in passive bleeding from the kidney, does not seem to be applicable to cases of injury in which inflammation is present. The presence of blood in the bladder does not usually occasion much trouble; it did so in the patient from whom this blood passed, and I was obliged to wash out the bladder to free it from coagula and enable the urine to escape, not after an accident indeed, but for fungus hæmatodes of the kidney. With a double catheter and warm water there is no difficulty in doing this, if you are obliged; at all events there can be no occasion to perform the high operation, as for lithotomy, which was done in one case by Mr. Copland Hutchinson, where blood lodged in the bladder. In most cases, however, you may disregard the amount of hæmorrhage, and treat the case as you would another in which there was no bleeding, and you will find it cease gradually in two or three days. I need not say that rest is necessary, and with this you must employ antiphlogistic remedies. You see that our patient now in the house has been cupped once, and has had leeches also once, and fomentations to the painful side; and such means are usually enough. In the case,

however, which I read to you, of recent suppuration, I was obliged to bleed as often as five times; cupping, however, is generally sufficient. Then you saw that I gave calomel and saline purgatives; and if you have occasion for purgatives in these cases, and particularly when the lithates abound, as they did here, the salts you select should be the vegetable ones, the potassio-tartrate of soda, or the tartrate of potash, so that the alkalies may at once pass to the kidney and neutralise the excess of acid. Then, again, you may give saline draughts, and add to this sometimes some colchicum if the inflammation does not easily yield.

After the first symptoms have subsided, you must next look carefully for remaining pain and weakness in the loins, and use counter-irritants; apply blisters, taking the precaution of using some muslin or tissue-paper under them, in order that the cantharides may not be absorbed and pass to the injured or inflamed kidney; and finally, if such pain and weakness continue long, you should insert a seton or an issue over the affected part, which you will do with the view of preventing the formation of abscess or other chronic disease of the kidney, and also to obviate another future mischief, which has been pointed out by Mr. Earle, in a paper in the *Medico-Chirurgical Transactions*, namely, the formation of calculi in the kidney; though it does not seem very probable that these bodies would be deposited unless the patient's urinary secretion was otherwise disordered.

Such, then, is an account of the effects of injury of the kidney, which this case suggested to me as not unlikely to be useful, since I believe you will find little said about the subject.

In the short time that remains, I will draw your attention to some points in a case of hernia, on which I operated a few days ago, which is, in several particulars, very interesting.

Thomas Jackson, *set.* 36, was admitted May 10th, at 1 in the afternoon, with an incarcerated scrotal hernia of the right side. He has had a rupture since he was six years old, and has always been able to reduce it himself whenever it came down. He has always worn a truss, which he left off a short time ago, as it was broken. The hernia came down yesterday evening, and he was not able to reduce it. The tumor is of considerable size, containing, by its sound, air and fluid; the external ring is lax, but the stricture is apparently very tight at the internal one. No symptoms, except a slight disposition to sickness, without any vomiting, and some slight tenderness about the inguinal canal. I tried, for a short time, to reduce the hernia in the out-patients' room, and

then ordered him to be placed in a warm bath, and he was kept in for above half an hour; at 3 he was taken out of the bath, and I again tried the taxis without success, and the tumor was only a little less tense. Ice was then applied till near 6 P.M., when he complained of somewhat more pain from the ice, and the tumor was just as large and tense as before. A large injection was then given, and drawn off by a syringe, but without any effect upon the tumor. The pulse was 80, and no fresh symptom had come on. At 9 P.M. I again saw him; and finding quite as much hardness in the inguinal canal, and a little more pain, I then performed the operation. Our notes continue:—It was thought at first, by opening the external abdominal ring, that the tumor might be returned, sac and all; but this idea was abandoned, and the sac was opened, which contained only a little fluid, and then it was found that the tumor was composed of the cæcum, part of the colon, and the end of the ilium, with a large appendix vermiformis, which were all much distended with air. The stricture at the internal ring was freely divided, but nevertheless the bowel could not return till after manipulation for a considerable time, when the air having been at last pushed out of the intestine, the hernia went up. The intestine was quite healthy, and only slightly vascular. Two sutures were put in, and the parts lightly dressed. The patient lost no blood. At 10 o'clock, the notes add, he was relieved by the operation, and does not complain of pain, except a little in the bowels—near the wound in fact. Pulse soft, 68, with some intermission, and the tongue was rather tremulous.

Now in considering this case, the first point which may have struck you is the small extent of symptoms, which justified me, as I imagine, in operating: the intestine was scarcely strangulated. It might have been said by some that it was in a state of incarceration verging on strangulation; there was no sickness, no tenderness of abdomen, no alteration of pulse, no pain or tenderness of the whole tumor; there was none of the severity of symptoms such as would have been looked for when I was a student; still less was there redness and inflammation of the skin; and I actually remember a few years ago a report being published from the practice of a surgeon of repute, of a case as somewhat remarkable, because the operation was performed before there was any external sign of inflammation! I operated because in the absence of such further signs of strangulation the hernia contained intestine, and the inguinal canal was of considerable length, and very firm and hard, and the tenderness and pain of this part, slight as they were, compared with many cases, were on the increase.

With so firm a compression in the canal, not allowing any impulse or coughing to pass through, though the diameter of the neck of the tumor was considerable, you may generally be certain that you will not reduce it, and I strongly recommend you to operate before severe symptoms come on, as the safest plan for your patient, rather than wait till inflammation of the intestine has already commenced, which was always done a few years ago.

A second point to be noticed in this case is my abandoning my original intention of dividing the parts external to the sac without opening the peritoneum. My reason was this: there is one disadvantage attending this procedure in inguinal hernia, which I am sure has not been sufficiently dwelt upon: if you divide the tendon of the external abdominal muscle, and the lower borders of the two internal muscles, and the fasciæ, sufficiently to allow of the sac swelling out so as to shew you that the pressure which causes the stricture has been removed, you take away a great deal of the protection given to the abdomen after the common operation by these parts; the patient is sure to have a large hernia afterwards, and requires a large truss, which can still only with difficulty prevent the protrusion. If, on the other hand, the sac is opened lower down, the internal ring and neck of the sac can be divided as freely as you wish, while enough is left to cover the canal afterwards, and enable a common truss to keep up the hernia. On exposing the external ring in this case I found that the tendon and other parts were much spread out, giving great length to the canal, and I did not therefore proceed in this way, but opened the sac below the external ring in the common way. I believe, indeed, that I should certainly have failed in reducing the hernia, if I had gone on as I first intended, even with a very large incision: I have tried it, and seen it done by others several times in old inguinal herniæ, without success, although the parts have been so fully divided that the neck of the sac has quite bulged out on the pressure being removed; and yet the stricture remained, because it was formed by internal projection of the neck of the sac; besides which, there is the chance of the stricture being actually situated in the omentum within the sac; of which we have had three instances, I think, in the last twelve months. I say nothing at present of femoral hernia, and recent protrusions at any opening, but I think in old inguinal hernia the operation of opening the sac below the external ring is generally the best.

This case was in the third place remarkable from the nature of the contents, which consisted of the colon, cœcum, and adjacent ilium, with several inches of an appendix as

large as a small intestine. There have been several instances in the hospital lately, of strangulation where the colon has been found in the sac, and I have repeatedly had to operate in such cases. In all of these the reduction is very difficult, although the opening is large, and in many persons cannot be effected at all. The colon coming down brings with it its cellular connection to the parts behind; it slides down as it were, and is as much connected with the scrotum as it is in the loins to the parts there situated; the operation is therefore difficult, and great care is necessary not to open the bowel, which has half or two-thirds of its circumference without any sac at all. I have found only a little portion of sac on the upper and inner part of the tumors (where you must always try to open it), and the great bulk of the protruding part is attached to the vessels and cellular tissue, so that you cannot reduce it, and must leave it in its place, having divided the stricture, in hopes that it may go up by degrees in the same way as it descended. This was not, however, the cause of difficulty which I experienced in the reduction in this case, for the great intestine was protruded without any attachment; but what was remarkable, the great length of colon here found with the cœcum was as loose and free within the sac as small intestine commonly is. Whenever the cœcum is protruded there is a greater proportion of solid matter than there commonly is with small intestine; the valve of the colon and appendix vermiformis are very thick, and from the connexion which the ascending colon has within the abdomen, it is impossible to push up the great bowel first, but you must begin with the ilium and the valve, and make the cœcum and colon revolve, as it were, towards the centre of the cavity, as they cannot be pushed up straight into the abdomen. This was one cause of difficulty in this case, and another arose from the quantity of air contained in the cœcum, which drew down again what I got up. I could not, of course, squeeze up the air through the valve, and something or other prevented its passing upwards in the colon for a long while; when I did finally press the air upwards, the reduction was easily effected; with small intestine you can easily push up the air in both directions.

In the next place, as to the after treatment, there were here two dangers of opposite character to be guarded against, and what did good for one of these would make the risk of the other greater. In all cases of strangulated hernia you have necessarily to look carefully for the signs of inflammation of the peritoneum produced by the stricture of the protruding part; but besides this it was evident from the tremulousness of the man's tongue, and intermission of his pulse,

and from his acknowledgment when he was questioned in consequence of our observation on these signs, that this patient, a groom in Tattersall's yard, close to us, had led an intemperate life, and was just a fit subject for delirium tremens. We were therefore on our guard, and prepared to treat the earliest appearances of it; but the inflammation was the first danger, and fortunately for the patient no more depletion was necessary than that arising from some leeches to the part of the abdomen which became painful the day after the operation. I also gave him a grain and half of opium, and three grains of calomel, directly after the operation, and smaller doses were given him twice in the next 24 hours to obviate the inflammation present. You saw, however, that abstinence from his usual potations produced the effect we anticipated, and 48 hours after the operation he became furiously delirious; the attack coming on rather suddenly. Repeated doses of laudanum during the night had the effect, however, of quieting him, and setting him to sleep, and as the bowels were not then so open as on the previous day, I directed a turpentine injection to be administered. At my visit yesterday, the 13th, you saw that the opium taken in the night had so completely subdued him that the narcotism was even more than desirable, for he did not breathe more than eight times in a minute; it was striking, while he was in this state, to observe how thoroughly a few drops of water sprinkled on his face roused him to perfect consciousness, although I shook him in vain, even with some degree of roughness. To-day (the 14th), you see that he is going on quite well, free both from delirium and inflammation. Had it not been for the importance of the part affected, had it been the arm or leg for instance, I should have given him more stimulants and less narcotics; I did, however, order him some beef tea yesterday, and have directed a mutton chop to be given to-day.

The last circumstance I will allude to in the treatment of this case is the inflammation of the sac, which is not uncommon after the operation, particularly in those who have been accustomed to drinking, like our patient. When on the second or third day you find your patient become restless and irritable, and feverish, and his pulse varies in frequency, but yet is probably not so sharp and incompressible as in peritonitis (indeed it is sometimes soft in the circumstances I am going to allude to), and if the patient is sick, and the abdomen is flatulent, and above all, if he has shivering or distinct rigor, and there is a disposition to perspire after he has been hot and flushed, you are not to conclude at once that he has inflammation of the abdomen, but examine the wound carefully, and perhaps you will

see some redness of the edges, or if they have united perfectly, and are not red, yet you can feel a puffiness, and the patient has a good deal of tenderness: put a probe then between the lips of the incision, and a drop of dark pus will escape, if it has not already shown itself. In these instances you must immediately separate a part or the whole of the adhesions to let out the pus, and prevent the extension of cellular inflammation, which may otherwise go on to a great extent round the hip or down the thigh, or it may spread up below the muscles in contact with the peritoneum, which membrane thus becomes secondarily affected, though it may have escaped the effects of the strangulation. You saw then that I separated the whole of the adhesions on the second day (the 12th), before the delirium began, and the consequence of this was that the redness immediately ceased, and the wound, which was foul and sloughy, is already cleaning to-day (the 14th), and the man is going on well.

[There was in this case some return of pain in the abdomen on the day after the lecture was given, but it was immediately relieved by a few more leeches, and the patient is fast recovering (May 21st), with a diet of meat and porter.]

CASES OF STRICTURE OF THE URETHRA.

BY WILLIAM COULSON,
Surgeon to the Magdalen Hospital, &c.
(For the London Medical Gazette.)

I HAVE drawn up the following cases of stricture of the urethra* in the hope that a detail of the difficulties which they presented, and the means by which these difficulties were overcome, may not be unacceptable to the profession.

CASE I.—J. W. Esq., (solicitor), set 42, had been under my care at different times during the last seven years with stricture of the urethra. I had tried in vain the common and armed bougie; he had also at my request consulted one of the most eminent surgeons of the metropolis, but no instrument could be passed through the stricture. Under these circumstances, Mr. W. had made up his mind to try no further means. On being informed of some cases much resembling his own, in which the lancetted stilette had been tried with success, he resolved to come to town to have the instrument used on himself.

His symptoms at this time were a con-

* These cases were read before the Hunterian Society, April 17, 1844.

stant desire to void urine, attended with great pain and difficulty. The water sometimes flowed involuntarily, and when aware that it was coming he had no power to stop it. A few drops of urine generally remained in the passage, and these he was obliged to squeeze out by pressing on the perineum, or he suffered the greatest agony. There was considerable irritation of the glans penis, heat in the rectum, and pain in the back. His general health was pretty good.

Aug. 8th, 1842.—I examined the urethra, and found an impermeable stricture at the distance of five inches from the external orifice. I introduced the straight urethral perforator, and divided the stricture to the extent of half an inch. I then introduced a small wax bougie into the divided part, and told the patient to withdraw it when he felt desire to pass his water. The patient suffered very little pain, and lost only a few drops of blood. The following is his own account.

Aug. 9th.—“I felt tolerably comfortable all night. I kept in the bougie about three hours, and afterwards made water with tolerable freedom, though immediately afterwards I experienced great pain at the end of the penis for a short time.”

In the afternoon a wax bougie could be passed down the urethra five inches and a half, but not through the whole extent of the stricture. A slightly curved perforator was introduced by Mr. Stafford, and the remainder of the stricture at once divided. A No. 2 elastic gum catheter was then introduced into the bladder, and retained there all night.

Aug. 10th.—The No. 2 catheter was taken out, and replaced by a No. 4 gum-elastic one, which passed easily. Mr. W. had a shivering fit this morning, which was followed by feverish excitement. An opiate was administered as soon as the shivering came on, the patient having been provided with it in the event of this occurring: some aperient medicine was ordered to be taken in four hours: there was no local pain nor uneasiness.

Aug. 11th.—No. 4 catheter was taken out to-day, and replaced by No. 6. Has no symptom of constitutional disturbance.

Aug. 12th.—No. 6 was replaced by No. 8.

Aug. 13th.—I passed No. 11 gum-elastic catheter without much difficulty. In the evening Mr. W. withdrew the catheter according to my wish; he passed a very good night, but on the next morning when dressing to go to church he was seized with pain in the region of the bladder, frequent desire to pass urine, and the urine was bloody. By rest and the exhibition of small doses of morphia these symptoms subsided towards evening. The severe symptoms which occurred on this day are, I think, to be attributed to the too sudden increase in the size of the instrument last used.

Aug. 17th.—Since the 13th no instrument had been passed; the stream of urine is large, the urine is quite clear, and passed without pain. I introduced a No. 11 metallic bougie with ease, and retained it in the urethra for an hour. I instructed Mr. W. to introduce a bougie of this size for himself, and on the 25th of August took my leave of him, strongly advising him to pass the bougie once a week.

I received a letter from Mr. W. the latter part of last month, stating, that so great is the change, that he never remembers from the earliest days of childhood to have experienced the comfort and relief he now enjoys. He passes regularly once a week or oftener a No. 11 metallic bougie, which he can do with ease, and retains it in the urethra for upwards of half an hour upon each introduction.

CASE II.—Mr. E. æt. 57, consulted me at my house, Sept. 5th, 1842, for difficulty in passing his water. About six months ago he contracted a gonorrhœa, and three months afterwards he observed a slight impediment in making water; this varied considerably, being worse some days than others. Within the last month these symptoms were much aggravated; his water passed in a small divided stream, and at times would even dribble away. Not being able to pass the smallest size bougie further than 5½ inches, I at once introduced a curved lancetted stilette, and after three incisions succeeded in introducing No. 2 gum-elastic catheter into the bladder: no hæmorrhage took place, and the division of the stricture gave him very little pain. Mr. Markwick, my pupil, accompanied the patient in a cab to his residence a distance of nearly two miles. On his arrival at home, he went to bed, and was ordered to take a dose of morphia. The catheter was retained in the bladder.

Sept. 6th.—Feels tolerably easy. The instrument was not withdrawn.

Continue the morphia, if necessary.

7th.—I passed No. 4 catheter into the bladder with ease.

8th.—Has passed a bad night, and has had considerable fever, and complains of pain along the urethra. I withdrew the instrument, which gave him immediate relief. Bowels well opened.

Ordered a dose of morphia to be taken at once, and to be repeated, if necessary, at bed-time.

After this time no instrument was retained in the urethra, but at the interval of four days I passed, four times, No. 8 wax bougie with ease.

CASE III.—I was requested by Mr. Austin, surgeon, of Red Lion Street, to see a patient who had been labouring under stricture for some years, and which had been

recently much aggravated by an attack of gonorrhoea. The urine came away in the day either in drops or in a very small stream, and at night it flowed involuntarily, to the great distress and annoyance of the patient. On examining the urethra, I found a stricture six inches and a half distance from the external orifice. I tried, on several occasions, both large and small instruments, but never succeeded in passing one through the stricture.

I recommended the use of the lancetted stilette, and on the 14th October passed No. 6 curved stilette down to the stricture, and, after two divisions, was able to introduce No. 2 gum elastic catheter. The division of the stricture was attended with very little pain, and a few drops only of blood were lost. The catheter was retained in the bladder; on the following day it slipped out, but was again introduced.

Sept. 19th.—No. 2 gum elastic catheter was withdrawn, but a larger size could not at first be introduced. Here I may observe that no discharge had taken place from the urethra, an usual occurrence whilst the catheter is retained in the urethra, if the process of dilatation is going on.

The patient was extremely anxious for another division of the stricture, and I had actually introduced the lancetted stilette into the urethra for the purpose, but on holding the point of the instrument firmly against the stricture, it passed through the obstruction without the aid of the lancet. I then passed No. 6 silver catheter, which was retained in the bladder forty-eight hours.

21st.—No. 6 silver catheter was withdrawn, and easily replaced by No. 9 silver catheter. This instrument was only kept in the urethra for two hours.

The patient experienced very little local uneasiness, and no constitutional symptom whatever, from the treatment of the stricture, although he had been confined to his bed ten days prior, from irritation of the bladder and kidneys, caused either by cold or the local affection of the urethra.

It usually happens that a strong desire to pass urine, attended with violent straining efforts, and inability to pass more than a few drops, with a sense of fullness in the lower part of the abdomen, cause the greatest suffering to patients labouring under impermeable stricture, but in the last and first cases related incontinence of urine was the most distressing symptom.

CASE IV.—Sept. 3d, 1842, I was requested by Mr. Barringer, surgeon, of St. John Street, to see a gentleman, æt. 57, who had great difficulty in passing his water. He stated that being on a trial about eighteen years ago, he was obliged to retain his water for a considerable time, and on attempting to make water afterwards he experienced very

great difficulty and pain, from which time he was frequently obliged to pass an instrument to evacuate the bladder, as on the accession of cold, or derangement of his health, the urine could only be passed with very great difficulty. Within the last two or three months he had become much worse, and at the present time he makes water drop by drop, and with great pain: there is a hardened mass in the perineum extending from the scrotum to near the anus, and of the size of a man's fist: on examination per anum the prostate is found to be much enlarged. The smallest sized bougie could not be passed along the urethra further than 5½ inches.

Sept. 5th.—I introduced the curved lancetted stilette, and made two incisions, but no progress was made through the hardened mass; hæmorrhage, to the extent of five or six ounces, took place. A dose of morphia was given, and cold cloths applied to the parts.

6th.—I introduced the instrument again, and, after making three incisions, succeeded in getting down to about seven inches. No. 4 catheter was introduced, and pressure was made with it for about an hour, when it reached 8½ inches, and was then retained for some hours, during which time the urine passed through it. Very great force was required to withdraw the instrument, and it was much bent. The morphia was continued every four hours.

7th.—Passes his water in a small stream, and with less pain. I again introduced the lancetted stilette, and succeeded in getting to the extent of eight inches, but so much force was required to withdraw the instrument that it broke, the broken portions of the instrument being kept together by means of the wire attached to the lancet: the patient observed, that no vice could hold the instrument so firmly as it was held by his stricture.

The morphia to be continued.

8th.—Has passed a bad night, and had considerable fever; there is no amelioration in the stream. I endeavoured to pass a small bougie, but could not succeed. The morphia to be continued. Considerable irritation succeeded the last division of the hardened mass. I advised that no more trials should be made for the present with the lancetted stilette, but that we should wait to see if suppuration would take place. About two days after this, fluctuation was felt in the perineum at the posterior part of the hardened mass. I opened this part, and a small quantity of purulent and urinary fluid escaped. This discharge reduced, in a slight degree, the swelling in the perineum, and relieved, for a short time, the symptoms. After the lapse of three weeks the patient was again anxious for the use of the lancetted

stilette, and I advised him to see Mr. Stafford.

29th.—Mr. S. introduced the curved stilette to the extent of five inches, and made several incisions, but could make no progress through the hardened mass. The sensation produced by the propulsion of the lancet through this structure resembled the cutting of intervertebral substance. No hæmorrhage ensued.

Oct. 2d.—Passed a restless night: his symptoms became worse: greater difficulty in making water; pain in the region of the bladder, and considerable accession of fever.

3d.—Nearly complete retention had now ensued; only a few drops of urine could be passed, and these with great pain. Under these circumstances I determined on cutting down on this hardened mass from the perineum. The patient being placed in the same situation as in the operation for stone, a small staff was introduced into the urethra as far as it could go, which was to the extent of five inches: an incision was made from the inferior part of the scrotum to the extent of the mass, which reached to the sphincter ani: the staff was depressed, and pushed through the divided mass, the point being near to the membranous part of the urethra. There was considerable difficulty in getting beyond this point; but by means of a long blunt-pointed lithotomy knife, the point being kept in the groove whilst the staff was pushed towards the bladder, and the rectum being guarded by the finger, the remainder of the stricture was divided, and a No. 5 silver catheter introduced into the bladder.

5th.—The patient felt greatly relieved after the operation; but diarrhoea came on, which lasted some days, and was only checked with great difficulty by large doses of camphor and opium: this, together with his previous sufferings, reduced him very much. An abscess formed above the pubes, and another on the inside of the thigh, both of which were opened, and discharged large quantities of pus.

14th.—No. 5 catheter, which had been retained in the urethra nine days, was removed, and replaced by No. 7.

18th.—No. 7 was removed, and replaced by No. 8, which was kept in for three days. Since this time the instrument has not been kept in, but a No. 10 silver catheter is passed every three or four days.

The wound in the perineum is now (November) quite healed, the patient makes water in a full stream, and his general health and strength are restored.

CASE V.—Mr. D., aged 47, applied to me for an affection of the urethra. For the last five or six months there had been a copious discharge from the urethra, scalding sensation in making water, with painful erections. The urine dribbled from him,

or came away in a very fine stream, and the difficulty of passing it had of late very much increased. His general health was considerably deranged; pulse weak, countenance pale and emaciated, tongue white, and occasional shivering fits. The patient had, for the last three or four months, been under the care of a surgeon, who frequently introduced a bougie for him, and he had frequently introduced one himself, but his symptoms had not at all amended. Finding his health so much deranged, I postponed the passing of the bougie, and gave him some quinine, by the use of which his health was much improved. After a week or two I tried a small bougie, which passed with great ease. On withdrawing it, however, I found the end of the bougie smeared with feces. I pointed this out to the patient, and informed him that the instrument had not passed into the bladder, but into the rectum. He then informed me that he had often observed the same appearance. I then re-introduced a bougie, and putting the fore finger of the left hand up the rectum, felt the end of the bougie: the opening was small and valvular, for no urine passed through the rectum, nor any feces through the urethra. He was seen by an eminent surgeon, with me, who could pass no instrument through the stricture; and, without great care, it passed through the opening into the rectum. We determined that a full-sized armed bougie should be introduced once in four or five days, and that the point of the instrument should be kept towards the upper surface of the urethra, so as to avoid its entering into the rectum. By this plan of treatment the patient recovered after four or five applications, and continues to this time quite well.

REPORT ON THE ROYAL MATERNITY CHARITY.

By F. H. RAMSBOTHAM, M.D.

(For the London Medical Gazette.)

[Continued from page 226.]

DURING the year 1835, there were delivered in the Eastern District of the Royal Maternity Charity, under the superintendence of Dr. F. H. Ramsbotham,—

2311 women—Of which cases,

16 were twins—about one in every 144 cases: of these, in 8 cases both heads presented; in 4 the presentation was head and breech or inferior extremities; in 3 both breech or inferior extremities; and in one case the

breech and shoulder presented. In 3 of these cases both children were males; in 6 both were females; and in 7 they were of different sexes.

1229 children were males.

1098 children were females.

2437 were presentations of some part of the head: of these 8 were face-presentations—about one in every 291 births; and one was an ear presentation.

57 were presentations of the breech, or some part of the inferior extremities—about one in every 41 births; of these 11 were twins.

7 were transverse presentations—about one in every 332½ births; all of the shoulder, or some part of the upper extremities. Three of the children were born alive; they were all except one delivered by “turning;” in that case decapitation was performed. The membranes had given way 48 hours before I was called; but there had been very little uterine action till within the last two or three hours, and the presentation had not been detected. I found the right hand external, and the uterus contracted forcibly round the child’s body: with difficulty I brought down a foot, but could not get the body to revolve. As putrefaction had commenced, I passed my father’s hook round the neck, and with much trouble decapitated the child; the body was immediately extracted, and the head and placenta soon followed. At the time the operation was commenced the child’s body lay entirely above the brim of the pelvis, which was narrowed in its conjugate diameter. Soon after her delivery the woman was seized with a violent rigor; symptoms of uterine inflammation supervened, and she died on the third day. Though I was as careful as I could be in the use of my instrument, I feared the uterus was injured. Another woman died on the third day after delivery by “turning:” the operation was performed by one of the district surgeons, and I have no history of the case.

In 3 the placenta was implanted over the os uteri—about one in every 776 cases; in two the mouth was entirely, and in one partially, covered by the mass; two of these patients were delivered by “turning,” the head presenting; in the other case the breech presented: all did well: two of the children were born dead.

7 were complicated with alarming

accidental hæmorrhage before delivery, *not* the result of placental presentation; about one in every 330 cases. In all these cases the hæmorrhage was arrested or materially diminished after the membranes were ruptured, and the children were born naturally—6 of them still; one alive. One of the women died from the effects of loss of blood on the 11th day after delivery.

In 8 the placenta was retained within the uterus, either by irregular contraction or atony of the uterine fibres, or by morbid adhesion between the uterine and placental surfaces, requiring the introduction of the hand for its removal—about one in every 289 cases: with all there was more or less of hæmorrhage; one was premature: all the women did well.

5 were complicated with alarming hæmorrhage after the natural expulsion of the placenta—about 1 in every 462 cases: of these 1 was premature, a breech presentation; another was a twin case. All the women did well.

I was delivered by craniotomy: it was a primary labour, and there was a narrow pelvis.

3 were delivered by the forceps; 1 by the long, the others by the short instrument—about 1 in every 776 cases. In the former case the child was dead; in the latter both were living. All the women recovered. They were all primary labours.

4 were complicated with puerperal convulsions—about 1 in every 578 cases. The attack occurred, in all these cases, during labour. All the women were delivered naturally; they were all benefitted by bleeding and purging. In 1 case delivery put a stop to the paroxysms; in 3 they continued for some time after. One woman had more than fifty fits, two only happening before delivery. 3 of the children were expelled dead; one living. All the women recovered.

In one case premature labour was induced, in consequence of the woman possessing a small pelvis. She took the ergot for three days, at the end of which time the os uteri was dilated to the size of a shilling, and softened: as the head was discovered to be presenting, I then ruptured the membranes: pains came on forty hours after, and she was delivered of a living child in fifty-five hours from the time the waters were discharged.

7 women died, either from puerperal causes or within the puerperal month—being 1 in about every 330 cases.

2241 children were born living.

86 children were born dead—being 1 in about every 27 births.

Of the Deaths,—

1 was eleven days after labour, from the effects of hæmorrhage; there had been a draining of blood for some weeks previously.

2 after delivery under shoulder presentation, both on the third day; one after the operation of version had been performed, and one from hysteritis after decapitation.

1 on the eighth day after labour: she was attacked with apoplexy, originating in violent mental agitation, six days after her labour, and died in less than forty-eight hours.

2 from malignant puerperal fever, at that time prevalent; one on the ninth, the other on the fifteenth day. They were both attended by the same midwife, who also, during the same month, lost two private patients in the same disease.

1 from peritonitis, thirty-one days after delivery.

Of the Still-born Children,—

26 were premature.

6 were putrid, at full time, or nearly so.

16 were breech presentations, at full time, or nearly so.

4 were transverse presentations.

With 5 the funis prolapsed: four by the side of the head, and one by the breech.

1 was delivered by craniotomy.

1 by the forceps.

2 under placental presentation.

6 were delivered after violent accidental hæmorrhage.

3 under lingering labour.

3 under convulsions.

2 were acephalous.

11 were at full time, not putrid, head presentations, not delivered by art.

In this year district-surgeons were appointed to the Charity, to whom the midwives generally apply in the first instance, when they require assistance. Many of the cases of difficulty, therefore, which happened subsequently to this date, I have not myself seen; but as I am in constant communication with these gentlemen, and as the midwives' books are laid before me every month, I can equally vouch for the correctness of the statements.

CONTRIBUTIONS

TO THE

PHYSIOLOGY OF THE HUMAN OVARY.

By CHARLES RITCHIE, M.D. Glasgow.

[Continued from p. 142.]

SUMMARY.

1. The fallopian tubes of the infant, and of the child before puberty, are perfect in their structure, although their patency is more or less obstructed at birth by the presence in them and in the uterus of a tenacious glue-coloured mucus; and immediately before the establishment of menstruation, and throughout adult life, they are occupied, and have their uterine extremities in particular distended by a cream-looking fluid similar in appearance to the ordinary vaginal secretion, and which, as observed by the microscope, consists of innumerable very minute globules aggregated into masses usually of an oval form, and possessing a specific character different from the globules either of blood or of pus. Part I., Sect. I., 1, 2, 3, 4, 5; Sect. II., 5; Part II., Sect. I., 1.

2. The ovaries of new-born infants and children are occupied, sometimes numerous, by Graafian vesicles or ovisacs, which are highly vascular as early as the sixth year, and vary in size from the bulk of a coriander seed to that of a small raisin, in the fourteenth year, at which time, also, they are filled with their usual transparent granular fluid; their contained ova can be detected, and their coats are so elastic, that their contents, on their rupture, may be projected to at least twelve inches: the existence of menstruation not being essential, therefore, to these conditions, either as a cause of them or as an effect, and the possibility, even at this age, should rupture of the follicles occur, of their contained ova being conveyed to the uterus along the fallopian tubes, kept patent by their peculiar secretion, will be admitted. Part I., Sect. I., 1, 2, 3, 4, 5, 6, 7, 8, 9.

3. The Graafian vesicles contained in the ovaries prior to menstruation are found, as they also are in every other period of life, in continual progression towards the circumference of the glands, which they penetrate, discharging themselves by circular-shaped

capillary-sized pores or openings in the peritoneal coat (Part I., Sect. I., 2, 3, 4, 5, 6, 7, 10); the presence of the catamenia being thus no indispensable prerequisite to their rupture.

4. The establishment of menstruation does not necessarily give rise to any immediate modification in the manner in which the ovisacs are discharged, or in the subsequent changes which these bodies undergo; but in some cases the conditions which obtain in the period before puberty are extended for a time, like that of menstruation. P. I., S. II., 1, 2.

5. The ovisacs of the healthy menstruating female are, as a general rule, larger, and more injected with red vessels, than they are previous to the setting up of that condition; but such change may have interposed a transition state in which the appearances peculiar to both, or the small-sized vesicles of the interior of the ovaries, the miliary copper-coloured maculæ, the numerous but delicate vesicular elevations and punctiform openings of the surface, of the infantile period, and the pisiform, turgid vesicles, the organized cysts, and the angular or linear cicatrices of the menstruating, are intermixed. P. I., S. II., 3.

6. Menstruation gives rise to a congested state of the uterine vessels, manifested by a redness and increased vascularity of the vagina, and by the production on the internal surface of the cavity of the uterus of a mesh-work of deciduous villous vessels, which may remain for at least two weeks. P. I., S. II., 1, 2, 3, 4, 5; P. II., S. VII. *passim*.

7. The progression of the Graafian follicles, or ovisacs, towards the surface of the ovaries, their appearance under the peritoneal coat as copper-coloured macules, the absorption of that membrane, and of their own tunics, and the occurrence of a solution of their continuity at the point at which they unite, take place in the menstrual, precisely as in the anti-menstrual life; but in the former the vesicles are increased in bulk, vascularity, and organization, so that in their rupture there is generally a greater lesion of the peritoneum, and, after the escape of the ovulum and granular fluid, a larger effusion of blood into the vesicular cavity, and more remarkable subsequent changes in the coats of the ruptured cysts than in the

non-menstrual state. P. I., S. II.; P. II., S. VII.

8. The shape assumed by the ovisacs is circular, elliptical, or triangular, according very much as they occupy the body of the ovary, its margins, or the central point of its free edge; and the cicatrices left by their discharge are often irregularly linear or circular, according to the same circumstances—*passim*.

9. The ovisacs of the human female do not require the establishment or presence of menstruation for their development or rupture. Vesicles of adult size may exist and be discharged about the age of puberty, as also at other periods of life, independently of menstruation; and this state may be present in its normal form for at least eight consecutive periods, without a vesicle being ruptured, unless after the manner, and with the phenomena, which occur in childhood. P. I., S. I. 6, 7, 8, 9; S. II., 1, 2; S. III. IV. V.; P. II., *passim*.

10. The only circumstances essential to the discharge of ova are the rise of the vesicles which contain them to the surface, and the gradual thinning of the ovarian peritoneum, and of the coats of the ovisacs at their point of union: and although, from the augmented circulation of blood in the uterus at the menstrual period, it is possible that the rupture of vesicles which are thus prepared may happen more frequently at that than at any other time, there is yet no reason to suppose that it does so then exclusively, or that it may not take place during the intervals, menstruation being often present without any such rupture. P. I., S. II., 7, 8; S. III., 1, 2; S. IV., 1, 2, 4; S. V., 1, 2; P. II., S. III. 1, 4; S. V. 4, 5; S. VI., 4, 7, 8; S. VIII., 1, 7, 11; S. VIII., 1, 5.

11. The appearances presented by the ovaries, Graafian vesicles, and by the blood which is contained in the latter subsequent to their rupture, vary according to the time at which they are examined, and the absorbing power of the individual.

12. In cases of the recent evacuation of an ovisac the peritoneal coat of the ovary is occupied by a jagged slit or opening, having a florid vascular areola; in those of longer standing the opening is covered over, with the exception of a minute circular foramen in the

centre, or, where the slit has been of great length, of two such openings, with new tissue, surrounded by a claret-coloured margin; and in those still more ancient, the whole is healed up into a cicatrice, which is more or less superficial, and free from discoloration according to its age.

13. With respect to the blood which is generally contained in the ruptured vesicles, it is seen at first as a florid coagulum, next having its centre only scarlet-coloured, and its periphery more or less black, and perhaps furrowed; frequently the clot has a gamboge colour, from the decomposition, or has become pale from the absorption of its red globules; and lastly, the clot is found in different stages of absorption; but it sometimes also happens, and that indifferently in every variety of the uterine state, that the ruptured follicles are found empty, or containing only an aqueous fluid.

14. The coats of the ruptured ovisacs have been found in four different general conditions, apparently dependent on the relative degree of organization, and each class presenting, also, modifications of their respective characteristics, proceeding partly from the same cause, and partly, also, from changes connected with the period of their progress in which they were examined.

15. The first class was distinguished by the attenuated state of the coats of the ruptured ovisac, and by the total absence of any organic changes in these different from their condition previous to their discharge; the only alterations observable being,

A. The mechanical dying of their coats of an inky black colour, proceeding from their contact with their contained decomposed blood, and which bodies have in the descriptions been denominated *corpora nigra*. P. I., S. II., 1, 7; S. IV., 4; S. V., 2; P. II., S. I., 1, 4; S. II., 3; S. III., 4; S. IV., 1, 3; S. V., 3, 5; S. VII., 2; S. VIII., 1, 5; S. IX., 1, 3.

B. The dying of their coats of a yellow tint, from their enclosed clot of blood having become converted into a rust-coloured pigment, not unlike some of the denser sputa of acute pneumonia. These I have taken the liberty of calling, in the grammatical sense, *corpora lutea*, omitting at the same time the use of this term in its ordinary scientific

meaning. P. I., S. II., 9, 10; S. IV., 5, 6; P. II., S. V., 1, 3; S. VII., 1; S. VIII., 4.

This first class of ruptured ovisacs was found indifferently in all ages and states subsequent to puberty.

16. The second general class of ruptured vesicles was characterized, in addition to the presence of blood within their cavities, or, sometimes, when this had been either partially or entirely absorbed, of a black or of a yellowish stain, by organic changes in their coats, consisting, progressively, of an increased vascularity, a thickening, a whitening of the colour, and, finally, a corrugation of their tissue, and was observed,—

A. Under the form of soft white bodies of a yellowish, fatty aspect, having the outer coat much thickened, while their inner remained as a delicate diaphanous pellicle. P. I., S. II., 10; S. IV., 1, 3, 5; S. V., 2, 4; P. II., S. IV., 5; S. IX., 2.

B. As dense white bodies of a whitish, shining, firm structure, their inner coat being the seat of these changes, and their outer adhering loosely as a transparent, pellicular layer. P. I., S. IV., 3, 6; P. II., S. III., 4; S. IV., 1; S. V., 4; S. VI., 7, 8, 9; S. IX., 1, 4.

A. The discharged ovisacs which constituted the soft white bodies were seen—

1st. At a very early period after their discharge, their walls distended with a coagulum, and painted with turgid vessels, but not being divisible into layers. P. I., S. II., 4, et passim.

2d. In a similar state, except that the inner membrane had a swollen, puffy look, and from the looseness of its adhesions to the more external layer, could be easily gathered into folds. P. II., S. VII., 2, et passim.

3d. At a period so advanced that the clot had become uniformly black and solid, the inner layer was easily separated from the more external, which was also thickened and become of a yellowish colour, having a resemblance to the walls of an artery. P. I., S. II., 5, et passim.

4th. At a point still more advanced, the outer, thickened, yellowish coat, had become corrugated into wrinkles or folds projecting into the cavity and covered by the soft inner layer, sometimes dyed yellow or black, as at 15 A. B. P. II., S. VII., 3.

5th. At what appeared to be yet a more lengthened period, the cysts were converted into yellowish-white, and generally globular bodies, more or less fissured from their contraction, and sometimes in process of absorption, having a granular looking structure, and seldom being divisible into laminæ by simple dissection. P. I., S. V., 2, 4; P. II., S. VII., 9.

B. The dense white bodies were seen—

1st. With inner layer still vascular, but thickened. P. II., S. VII., 12.

2d. With vessels of inner coat nearly obliterated, and it converted into a tenacious membrane of the thickness of writing paper. P. II., S. VII., 11, or S. V., 4.

3d. With inner layer of ovisac as a thick, opaque, deeply wrinkled or corrugated, and rocky cyst, or, sometimes, partially diaphanous, and of a shining, pearly aspect, and very white colour, most generally empty, but sometimes containing a yellow, or greenish, transparent fluid, or a clot of blood, either unchanged, or converted into a yellow or black pigment (as at 15 A. B.), the outer layer of the sac being a mere film or pellicle. P. I., S. IV., 6.

17. These white bodies (*corpora albida*) were found in every variety of uterine condition subsequent to the establishment of menstruation, but never before it, and the dense kind especially were persistent for a long period.

18. White bodies, as such, had no necessary connexion with the gravid condition, but occasionally they were, especially the dense variety (the *corpora lutea* of Baer), the only specialty observable in the ovaries of the puerperal female some time after delivery.

[To be continued.]

NEW APPLICATION OF THE REFLECTING PRISM.

To the Editor of the Medical Gazette.

SIR,

THROUGH the medium of your widely circulated journal, I take the liberty of bringing under the notice of the profession a new application of the principle of illumination derived from prismatic reflection, to the examination of disease in the dark passages connected with the open cavities of the body.

As a description of a mechanical in-

vention, a communication* was made by me on the subject to the Royal Scottish Society of Arts last week; but I desire to take the earliest opportunity of submitting the contrivance to the professional public, in the hope that it may be found to afford assistance in the investigation, and facilities in the appropriate treatment, of several important classes of diseases, which, by their situation, are naturally removed from view, and from that intelligent cognizance which is requisite to a correct pathology, the only basis for truly scientific treatment in the living body; and I confidently hope that the utility of the invention will be further verified by the experience of the profession at a distance, as it has already been by those of my brethren here, who have had an opportunity of observing for themselves.

It may be proper to remark, that I, in common with many others, have often felt the defectiveness of our professional resources for affording light to permit an examination of the nature of a variety of darkly seated affections, which are daily coming under the notice of the practitioner. My attention was specially awakened to this subject by the difficulties attending a case which came under my notice in November last; and I thereafter directed my attention to the devising some means of supplying its defect. The case to which I allude was chronic disease of the ear, attended with discharge, and much impaired hearing, of three years' standing, and my aim was at first confined to the construction of an instrument adapted to that part of the body; but the principle which I hit upon I soon found to be capable of being greatly extended, and applied to the examination of disease seated in parts still more remote from observation, and to which actual inspection has not before penetrated in the living body.

The means I employed for effecting the purpose are based on the principle of illumination by means of totally reflecting prisms of flint glass; and in order to render it intelligible to the reader, I have appended a diagram of

* "Description, with illustrations of a Totally Reflecting Prism, employed for illuminating the open cavities of the body, with a view to facilitate the examination of disease, and the application of remedial means in such situations." By Adam Warden, M.D. F.R.C.S.E. Communicated by Andrew Fyfe, M.D. F.R.S.E. &c."

the instrument constructed for making examination of the auditory canal,— as an inspection of that instrument, in connection with what I have to say

with reference to the extension of the principle, will suffice to satisfy any one of its general applicability.

The narrow and indirect tract of the external auditory canal, and the hairs with which it is commonly beset, are, as is well known, the natural obstacles to a correct view of its inward course and termination. By the aid of the *speculum*, and owing to the moveable state of the cartilaginous portion of the tube, these difficulties in the way of observation are readily obviated. Sufficient light, however, to illuminate the yet dark passage remains the one desideratum, without which, to exhibit the actual condition of the membrane of the tympanum, the surgeon cannot pronounce as to the importance or curability of disease, nor resort, with confidence of its safety from danger, even to the popular remedy of the syringe.

Before describing the method of illumination which I have found fitted satisfactorily to fulfil this end, I beg to notice that, according to my experience, preternatural constriction of the auditory canal, from morbid thickening of its walls, exists to a greater or less extent as a complication of chronic disease of the external ear, and by forming a physical impediment to the access of sound, all measures directed to restore the functions of hearing, irrespective of this condition of the passage, must prove comparatively ineffectual. The instrument which I submit to your notice is therefore formed with the view of its being adapted not only to the different development of the organ of hearing in youth and age, but also so as to form a series of dilators, applicable to the removal of stricture, upon the same principle as regulates the treatment of the same disease in other situations.

The instrument devised and represented in the accompanying diagram, consists of a straight arm, *a a*, five inches in length, terminating in a ring *b*, of half an inch internal diameter, the ring grooved in its interior as a screw. To this screw are adapted four canulæ or straight tubes, *c*, of four, three, two, and one lines calibre, and another, *d*, of a funnel or tapering shape, applicable for preliminary exploration, and removal of any accumulated cerumen obstructing the passage of the light, also for affording a proper field for the passage of instruments, and for other topical manipulation. From the middle of the straight handle arises a curved branch *e*, and moveable in a pivot

joint at *f* toward the other side of the handle. This branch forms a stalk on which a prism of flint glass *g* is perched erect, on the level of the opening of the affixed canula. The prism rests in a metallic socket, and is made to revolve on its own axis at the touch of the finger, or to remain fixed in any desired position, by the aid of a small clamping screw, *h*. The instrument is thus complete for use. The canula is to be introduced into the ear to be examined, the patient being seated exposed to a good light. The surgeon placing himself conveniently opposite to the side of the patient, a face of the prism is turned towards the light, and it is made to revolve until the luminous spectrum is conveyed to the bottom of the canula, and to the surface sought to be observed. There is no difficulty in the adjustment of the position when the new relations of the light and of the object are familiarized by a little experience; and when once this adjustment is made, the full and clear illumination of the object is at once obtained, and with a degree of brilliancy exactly proportioned to the quantity of light employed in the particular observation.

The principle or theory consists in *total reflection*: the light is received by one side of the prism, is reflected from the second side, and emerges by the third side to the object illuminated, as represented by the dotted lines *x y z*, and whence its view is revealed to the eye. The illumination is not preternatural or dazzling, such as would alter the real features of disease, but natural, and such as the eye is familiar with. The advantage of this flat natural light will be fully appreciated by professional eyes; and I am persuaded, from ample experiment, that any means of concentrating light by lenses, or converging mirrors substituted for the prism, would not improve the serviceableness of the instrument exhibited, although by their subsidiary employment they may be made to contribute to its efficiency, whenever, under extraordinary circumstances, more intense light is required.

The method of illuminating diseased parts by the medium of the prism is relieved from the intricacies inseparable from the employment of a reflecting speculum, whose curve must be anew adapted by the manufacturer to the focal distance of the object to be viewed, otherwise it is indistinct and distorted,

- as in a false mirror. Neither is the method invented by me liable to the objections applicable to various ingenious contrivances for the same end, which we owe to distinguished members of the profession. By the convenient position of the light in prismatic illumination, it is not liable to be intercepted by the shadow of the observer, as is the case with any direct light proceeding from behind him,—a disadvantage we are not free from even where sunlight is employed; and if a lamp and lens be placed between the eye and the object viewed, not only does the dazzling artificial medium alter the characteristic aspect of disease, but such apparatus, in order to guide any surgical procedure, must be kept strictly in such a position as necessarily to interfere with any convenient measures in the removal of foreign bodies, or other manual operations. By a construction of instrument suited to the situations of disease in the different cavities, increased facilities in surgical practice, I feel warranted in asserting, are largely attainable through the adoption of the method proposed by me.

It will not fail to appear of no small moral importance, that by this method of obtaining observation and applying satisfactory treatment in the uterine diseases of females, the withdrawn position as it were, of the light, is calculated to lessen the misery attending all professional interference in such cases.

In conclusion, I may mention, that I have satisfied myself by varied experiments that a Totally Reflecting Prism placed in the angle of a bent canula, and illuminated by a second prism, in the manner already described, will afford a satisfactory view of objects whose situation precludes the possibility of direct observation—such as the opening of the Eustachian tube and of the glottis, the position of foreign bodies detained in the throat, &c. For the sake of illustration, I may state, that by a simple arrangement, consisting of two tubes, each twelve inches long and one inch diameter, embracing at their point of junction, at right angles to each other, a right-angled prism, I have been enabled to make inspection with the utmost accuracy of exquisitely coloured drawings of the morbid anatomy of the eye; obtaining by the arrangement described a reflection of

the image presented at the opposite extremity of such an instrument, and that in all the brilliancy of sunlight-view.

I hoped to have accompanied this communication with a view of the instrument, which is in course of construction here, under my directions, applicable to the survey of the region of the throat; but as it has already undergone several modifications, and is not yet fully conformable to my wishes, I must reserve my description of it for a future opportunity. Furthermore, I find that a diseased surface can be accurately inspected at the extremity of a straight tube of twelve inches long and a quarter of an inch diameter; and I indulge the hope that within this range a more satisfactory treatment of highly seated strictures and diseases of the straight gut, as well as of diseases of the urinary organs, may be thereby attained. That the latter expectation is not altogether visionary may be inferred from the fact, that the straight canula of the *brise-pierre* of Baron Heurteloup has a diameter of one third of an inch.—I am, sir,

Your obedient servant,

ADAM WARDEN,
M.D. F.R.C.S.E. &c.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abrégé.”—D'ALEMBERT.

Guy's Hospital Reports. New Series,
No. 3, April 1844.

(Second Analytical Notice.)

DR. OLDHAM furnishes a paper, entitled, “On Polypus Uteri, and its Co-existence with Pregnancy,” in which he also develops his peculiar views on the mechanism of menstruation, and of hæmorrhages from the unimpregnated uterus. Under the generic term “polypus,” he proposes to include all the different bleeding growths which spring from the fundus, body, cervix, or mouth of the uterus, and which either preternaturally distend its cavity, or protrude into the vagina, or even beyond the labia. He describes five varieties, and, from the consideration of their morbid anatomy, is led to regard them as

formed generally "not from an organized coagulum, or on the type of compound adventitious cysts, but as direct productions of the different elementary tissues of the uterus itself."

1. The pediculated fibrous polypus. When the common, hard, or fibrous tubercle, the most common growth to which the uterus is liable, grows inwards, it comes within the directing power of that organ, and is propelled downwards. It thus acquires a stalk or pedicle, and ceases to be the inert body, hurtful only by its mechanical action, that it was before, and becomes a baneful and bleeding tumor. This pedicle is more or less readily acquired, according as the fibrous growth originates immediately beneath the mucous membrane, or is more deeply seated, and covered by the proper uterine tissue.

This kind of polypus is composed of a fibrous growth, with more or less of uterine structure, covered by the mucous membrane. The anatomical elements of the fibrous growth are clear unstriated fibres, closely packed, interspersed in some instances with crystalline calcareous grains, and minutely divided capillary arteries running parallel with the elementary fibre. The amount of blood-vessels in the fibrous growth itself varies with its compactness and density. The arterial supply is scanty when the growth is hard and of long standing; but when more recently developed, large and numerous arteries proceed from the uterine tissue, and freely enter it; but not so the veins, for they are only closely collected around, but do not enter within it. The amount of uterine tissue varies: in some instances a thickish layer incloses the fibrous growth, but more commonly it is very thin around the free expanded surface, and collects in the stalk. The lining membrane of the uterus always forms the external investment, and is usually clear, thin, and smooth, but sometimes thick, and of that woolly flocculent appearance met with in various disorders of the uterus and ovaries.

The vascularity of this polypus resides essentially in the investing or connecting portion of the proper tissue of the uterus, which undergoes changes proportioned to the bulk of the fibrous growth. The arteries increase but little compared with the veins, which

enlarge greatly, and much in the same way as in pregnancy, gathering around the inclosed tubercle in a planiform manner, or densely collecting in the stalk.

Of this variety Dr. Oldham remarks, first, that the process of descent or pediculation may occupy years, or even destroy the patient, before it is completed. Secondly, that this polypus may occasion a clear serous discharge as well as hæmorrhage, the former as effectually draining the system and destroying as the latter; or that both kinds of discharge may alternate in the same patient: of which he details an instructive case now under treatment. And lastly, that the uterine action which effects the descent of the fibrous growth occasionally produces inversion of that portion of the uterus from which the polypus springs—a circumstance of great practical importance in attempting removal by ligature. Three preparations showing this occurrence he has himself seen, one of which is figured in illustration. The right horn of the uterus, with its orifice patent, is seen completely inverted by a polypus about the size of a small orange. It was taken from an unmarried female, between 50 and 60 years of age. It is also remarkable, because the lower part of the growth, which has passed through the dilated os uteri, is seen in a state of slough and ulceration; and on the right side there is also a large patch of fungoid growth, with a corresponding one, of the same size and character, on the contiguous surface of the expanded uterus.

The history of the cases where an inverted portion of the uterus has been included in a ligature, by Denman, W. Hunter, and others, is that of a fatal operation, with symptoms of uterine and peritoneal inflammation, phlebitis, and the absorption and circulation of pus. Dr. Oldham points out the symptoms which may lead the practitioner to suspect the presence, and eulogizes the aid afforded by Dr. Simpson's uterine sound (a new name for the old probe?) in determining the co-existence of partial inversion of the uterus with polypus, and judiciously observes, "that the occurrence of pain when the ligature is tightened, attended perhaps by vomiting, ought to be met, not by opiates to lull the pain, and so destroy this valuable indication

of impending danger, but by loosening the ligature and relieving the included parts."

The sloughing, ulceration, and development of malignant disease on the free surface of the polypus, coexisting with inversion of the uterus, as represented in the plate, leads him to remark, that polypi, like other pendant tumors of the uterus and vagina, are apt to ulcerate and break down. This process usually begins at the lower surface, at a point where the greatest pressure exists, and extends upwards, destroying the growth, which is voided piecemeal; but sometimes occurs in the pedicle, when the body is said to be spontaneously separated. Dupuytren, he observes, maintained that polypi which had lain long in the vagina had a tendency to undergo cancerous degeneration,—in some instances by a transformation of the growth into a cerebri-form matter, and in others, as in this case, by the generation of fungoid patches, with a softening of their structure. Dr. Oldham then introduces a case furnished by Dr. E. Rigby, where the uterus apparently became suddenly inverted after tying a protruding polypus, and was removed with the polypus by a second ligature by that gentleman. The evidence that it was the uterus, is, however, far from conclusive.

2. The spongy, cellular, or fibro-cellular polypus. From his description we learn that this variety is so called from its appearing cellular when cut into. In some rare instances cysts containing a clear fluid or grumous blood have been noticed; but, in general, the apparent cells are really truncated, or divided veins, and it might not inaptly be termed a venous tumor. The thin and delicate veins are, however, surrounded and supported by an unstriped fibre, closely resembling, if not identical with, the muscular tissue of the uterus. They not only collect around the growth, and may be seen on the surface in large trunks, but penetrate and are distributed through the centre in large channels, which freely communicate with each other, and form a very extensive venous circulation. An illustrative preparation is figured where the polypus is seen growing upwards towards the fundus. This kind of polypus grows from any part of the uterus, frequently with a very slender

stalk, and is from the first of a soft and more impressible character than the fibrous variety. It sometimes acquires a very large size, and when associated with pregnancy, as in Mr. Crisp's case, which proved fatal, weighed seven pounds. The uterus does not readily yield, so that at first the polypus is seen flat, and accommodated to the small cavity; and it is only when it has escaped into the vagina that it expands and bulges out.

3. A polypus described by Dr. Lee (*Med.-Chir. Trans.* vol. xix.) This consists, in its interior, of a numerous collection of little round cells, supported by a fine fibrous tissue. The cells are about the size of Graafian follicles, tensely filled with a pellucid or semi-opaque fluid, and the cell capsule thin and transparent. The exterior is smooth, with numerous tense shining elevations. The specimen delineated is about the size of a Brazil nut, has a short pedicle, and grows from the body into the cavity of the uterus. Seeing that the uterine glands expand into cuplike cysts under the stimulus of impregnation and ovarian excitement, Dr. Oldham is disposed to regard this variety of polypoid growth as produced by these glands. The glands of Naboth have been observed in one instance, by Dr. Oldham, to produce an analogous formation at the lip of the uterus. They became transformed into a mass of round pearly-looking cells, blended together by a fine fibrous tissue, and were filled and distended to the utmost by a semi-opaque mucus, from obstruction of their mouths.

4. A form of polypus produced by enlargement of the cervix uteri. This has been described and figured in Dr. Lee's valuable paper. It consists of pendant cystiform bodies, clustered together, which are vascular, and filled with a curdy fluid. Dr. Oldham offers some suggestions on its treatment, and describes one in Guy's museum about the size of a walnut. It is a cyst with a cortical layer of fibrous tissue, and an irregular lining within.

5. The channelled polypus of the cervix. Dr. Oldham, in his investigations, has met with two specimens springing from the cervix, and in which the crypts with their tenacious mucus reappear; but which are so very different from the last described variety, that he proposes to call it by

the above name. The polypus was single in both instances, with numerous valvular orifices marked out on its exterior, while its interior was made up of many large channels, with occasional communications between them, and opening by the large orifices observed on the free surface. These channels contain more or less mucus, are lined with a thin rugous membrane, and are vascular. Both specimens are delineated.

Dr. Oldham next institutes an inquiry into the source of the alarming bleedings which polypi occasion. He observes, that "the peculiar circulation of the womb, which is eminently venous, and the disposition of the veins in planes, and not a gathering from capillary to small branches, and from them to larger, and their tendency to open by lateral apertures on the surface of the uterus during pregnancy, ought never to be forgotten in uterine pathology." When the unimpregnated uterus is injected, he finds the lining membrane is covered with a uniform capillary network, with some largish veins running just beneath the surface, and in a straight line from the cervix towards the fundus. Contrary to the views of Dr. Churchill, he regards the hæmorrhage as furnished by the polypi themselves, and principally from the veins on their surface or pedicle, which sometimes are lacerated, and at others open under accumulation of blood as they do during menstruation. The existence of vessels in polypi has been overlooked by Dr. Churchill and others, from the difficulty that exists "in recognizing the veins of the uterus when they have quitted their uterine bed, and been prolonged into any adventitious growths, or as a familiar example into the placenta; their very thin coats collapse, and their smaller divisions appear like a loose cellular structure. Their obscurity in the placenta has long been known, and unless they are well injected, it would be very difficult to recognize as veins those large oblique lateral channels placed intermediately between the margin of the placenta and the uterine veins, and returning the blood from the placenta into the general circulation." It is also embarrassing to make out the exact state of the veins during the function of menstruation, just as the demonstration of the muscular fibre

and the nervous ganglia, in a uterus where these elementary constituents are undeveloped by pregnancy, is one of acknowledged difficulty; but there is much circumstantial proof that menstruation is but a periodical enlargement and spontaneous opening of the veins on the inner surface of the uterus. Whatever difference may be said to exist between the menses and blood, as to the former not coagulating, being defective in fibrin, &c. (variations which its slow admixture with the salts, in the secretion from the uterine and vaginal glands, may probably cause) still its appearance under the microscope (carefully taken from two women with procident uteri), goes far to prove it a hæmorrhage, as the blood corpuscle is its main constituent. If a healthy uterus examined after death be squeezed, its lining membrane remains clear and perfectly smooth as before the pressure was applied; but if enlarged, from the congestion preceding or attending menstruation, or the development of a small tumor, the membrane when thus pressed shows a number of bloody points, which increase with the continuance of the pressure. The easy and frequent conversion of the monthly discharge into an undeniable hæmorrhage with clots, favours, and the venous openings when the womb is magnified by pregnancy, additionally confirm this view. Mauriceau observed, and Burton figured these openings in 1751; and in a conjoined experiment of Wallace, Johnson, and John Hunter, an injection of flake white and water thrown into the cavity of the uterus, when the fallopian tubes had been tied, and the arteries previously injected, found its way into the hypogastric and spermatic veins. From all these circumstances, Dr. Oldham regards the proximate cause of menstruation, as a filtering of blood from veins which open naturally upon the surface of the uterus; passive menorrhagia as a loss of power in the muscular fibre, which guards the orifices of these veins; the first bleedings in polypi, he ascribes to their general enlargement, and that want of accordance between vein and enveloping fibre, which a new interfering growth would be likely to produce; while the sudden bleedings which arise more capriciously, and without regard to the menstrual periods, take place either from

the tearing of the thin layer of mucous membrane which covers their free surface, and the orifices of the subjacent veins, or from the opening of these veins under the accumulation of blood much in the same way as the veins in the uterus do under the congestion of menstruation. Dr. Oldham has not yet succeeded in displaying the manner in which the veins terminate on the investing membrane of polypi, but has assured himself of the fact that in some instances they approach the surface not only as large long trunks, but more like a cellular or cavernous structure. Cruveilhier says, in one case, "several great uterine sinuses opened, on its surface at its apex, from which the blood flowed which destroyed the patient."

Dr. Oldham then proceeds to the consideration of polypus associated with pregnancy. This may occur in two forms:—1st, as a tumor depending in the vagina, and outside the cavity of the uterus; 2d, as retained within the cavity, and its existence unknown till labour has commenced or been concluded. The first form has been fully treated by Dr. Lever, in his *Essays on Pelvic Tumors obstructing Parturition*. When hæmorrhage has not demanded the removal of a polypus during gestation, it need not be meddled with during labour, unless its size mechanically prevents the passage of the child, when ligature and excision will prove the best means for its removal. He throws out the caution, that bleeding from a polypus may obscure the early signs of pregnancy, and the application of a ligature for its removal be followed by abortion; of which he narrates one instance, and has known several others. Of the second form, where the polypus is retained within the uterus, Dr. Oldham details six cases, four of which are furnished by Dr. Radford, of Manchester. He quotes two more from Dr. Churchill, two from Dr. Fergusson, and alludes to two others, for the purpose of illustrating its occurrence and treatment. A small polypus, he remarks, often exists in the cavity of the uterus, without producing any marked symptoms, and unless from some peculiarity of attachment, does not interfere with impregnation, but may become developed with advancing gestation. When conception occurs, the polypus immediately participates in the growth and

increased circulation of the uterus, particularly the venous, and grows silently within the cavity, which accommodates it without its interfering in any way with the process of foetal development, or showing any symptom of its presence. The labour has, in most of the recorded instances, been natural, and the uterus may close over the polypus without the occurrence of hæmorrhage or any untoward symptom; or the polypus may be expelled into the vagina, or beyond it, and there remain, decreasing with the diminishing uterus, and without causing hæmorrhage. This result ought always to be looked for; and it is an important practical fact to bear in mind, that a uterus which remains large, and evidently distended by something in its cavity after delivery, may contain a polypus, although a second foetus, or a coagulum, are the most ready suggestions; for the use of ergot of rye as a means to get rid of a polypus is likely to complicate the case, and peril the life of the patient. Where uterine action continues, and the hæmorrhage is unimportant, every effort should be made by sedatives, suppositories, and enemata, to quell it, and give the patient a chance for the spontaneous disappearance of the tumor. Should, however, violent hæmorrhages come on, or uterine pain persist, a prompt removal of the tumor will be necessary. For this purpose the application of a ligature, and excision immediately below that ligature, are recommended. Torsion has been employed; but the forcible tearing away of veins and fibre must be regarded as a dangerous expedient, likely to cause phlebitis and ulceration in a recently gravid uterus.

Mr. Bransby Cooper, who has performed lithotomy 84 times at Guy's Hospital, and upwards of 20 in private, with the loss of 10 patients, furnishes *Observations on Lithotomy*, which are commenced in the former, and completed in the present number. Twenty-seven of these cases are given in detail, eight of which were fatal. In four the operation was complicated with hæmorrhage, but not so as to prevent recovery. He employs the knife and straight staff. To lessen the danger of hæmorrhage, he opens the urethra at its membranous portion, so as to avoid the large artery of its bulb, and particularly insists that the fascial covering

of the left lobe of the prostate should not be divided by the knife, as the so doing inevitably leads to extravasation of urine into the cavity of the pelvis—the most frequent cause of failure of the operation. “He is perfectly assured that the incision through the prostate made by the knife should be no larger than just to admit the forceps; and that the finger of the operator, and the opening of the blades of the forceps, will be found the safest, and therefore the fittest, means of sufficiently enlarging the aperture for the extraction of the stone.” These observations comprise remarks on the causes and symptoms of stone, a brief description of the operation of lithotomy, which Mr. Cooper prefers when the stone is small, and the bladder capable of retaining from eight to ten ounces of water for a considerable time; but they are chiefly devoted to a pretty full description of the lateral operation, and the various complications and difficulties which the operator has himself experienced.

These papers are followed by a detailed Report of 47 hospital cases of Stricture of the Urethra, Retention, and Extravasation; and by another of 39 cases, illustrating Diseases of the Brain and Nervous System, as recorded in the books of the Clinical Society, and without preface, note, or comment.

The length to which our analysis has extended shows the practical value we attach to these Reports. May they long continue to appear, and stir up other institutions to send forth the like! We gladly award a full meed of praise to the lay authorities of the hospital, who so liberally cooperate with the zeal and industry of their medical officers, in furnishing the means of investigating disease on a large scale, and in communicating the results to the profession in an authorized and authentic shape. There is, however, a somewhat pompous array of five names on the title-page and cover as *editors*—an unnecessary division of responsibility; and the papers contain many objectionable repetitions, and much careless and colloquial phraseology,—blemishes which we should trust would disappear in future numbers, but that we fear such an editorial phalanx is impenetrable to literary criticism. It forcibly reminds us of the homely adage, “Too many cooks”—but we say no more.

MEDICAL GAZETTE.

“Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.”
CICERO.

THE NECESSITY OF HIGHLY EDUCATED MEN AS PRACTITIONERS OF MEDICINE.

THE matter of highest moment to the community in any legislative enactment touching the medical profession, is unquestionably the means that shall be taken to secure them in a succession of competent practitioners. As to the way in which the affairs of the Colleges or Companies with which the members of the medical profession may be associated, are to be administered, this signifies little to the world at large—whether there shall be one or several grades in each branch—whether all shall have a voice in the election of officers and governing Council, or only a privileged few, &c. &c.—all this, if not unimportant, which it is not, is still matter merely of secondary moment. What I ask of the government of my country, next to protection in person and property, is that such laws be made as shall secure me in the attendance of a competent adviser in case of sickness to me and mine; or, taking a wider and better view, passing from self, and catching a glimpse of the causes of disease and premature decay among the members of the community at large, made aware of all the evils that follow to individuals and society from inefficiency through sickness and untimely death, I ask farther of the government under which I live, to assure me the presence of men competent to advise with me as to the intimate nature of the causes of disease in general, and to show me the means by which they may be abated or removed.

The eyes of society have but just been unsealed in regard to the immense amount of remediable evil under which they have been content as yet to sit supine, and to look on as the will of God for their destruction;—as if he who had bestowed were not also willing that we should enjoy, and hold for long, his gift of present being! How shall men of the stamp required, men possessed of the knowledge which shall most effectually aid me, first individually, and then as a member of the body politic, be secured? There is but one answer to this question: **COMPETENT MEDICAL ADVISERS CAN ONLY BE SECURED BY THE CAREFUL CULTIVATION OF INTELLECTUAL FACULTIES NATURALLY OF THE FIRST ORDER.**

That "education forms the common mind," is a familiar adage; but in medicine common minds will not suffice; there must be native talent to begin upon. The perception of this truth is even as old as the history of medicine: the Asclepiades always required the youth whom they took as pupils to have given evidence of talent, and of natural bent towards medicine, before they received them as servants of the temple; and it was a wise and an excellent regulation. Native ability, then, in the first place; careful cultivation, most liberal education, in the second.

The subjects of medical science do indeed lie universally beyond the eye of the vulgar, beneath the surface of things; they have all to be toiled for, and are only to be won by long years of devotion to their research. If it be generally true, as the old Greek maintained, that "the gods sell all excellence to man at the price of immense labour," it is peculiarly true in reference to medicine. The studies of the medical man, indeed, embrace not merely the subject in which their results find application; but, inasmuch as this subject lives not independently and self-

sufficing, but, on the contrary, as he is influenced by, and intimately dependent on, every thing around him—the air he breathes, the food he eats, the circumstances in which he is placed, the means whereby, in the sweat of his brow, he earns his bread, &c.—so do the studies of the physician necessarily comprise all nature, so do they imply consideration of all that influences the bodily estate of man. We might even go farther, and say, that as man is not made up of body alone, but of mind, so attention to mental philosophy is fairly, is even necessarily, within the scope of the practitioner of medicine. "Out of the fulness of the heart the lips will speak:" and we of the medical profession in England know that, since the Roman Catholic form was superseded here, we do in fact serve as father-confessors to one-half of the community.—And here let us pause one moment, to cry honour on our brethren for the holy faith they have ever kept with all who have trusted them in the hour of trial; unbound by any oath, the confessional was never more sacred than hath still been with us the confided words of the sorely afflicted and the dying man; and we almost fancy—may we be pardoned for saying so—that the accents of trust and consolation we are enabled to speak, all-wanting in shape and method as of course they are, but grounded on reason, and the simple assurance impressed on our minds by the nature of our studies, of the being and attributes of God, are even as consoling to the sufferer as aught of ceremonial or more set form of imprecation. Oh! let the community take a large and liberal interest in its medical men, and own them as far removed, as heaven is high above earth, from vulgar empiricism and the traffic in nostrums—from homœopaths, and hydropathists, and mesmerists, and the host of purblind quacks,

and impostors with self-imposed blinkers, who waylay the ignorant to deceive them.

The community are indeed infinitely more interested in having a respectable and competent body of medical practitioners than in any other set of functionaries whatsoever. The well-educated medical man is now in fact the head and front of every measure having the social progress and the general welfare for its object; under his eye, and through his ministry, disease has long been on the decrease; and it is quite certain that the causes of disease and premature decay which are still suffered to exist, though easily remediable, are as legion in comparison with those that have been abated.

The most liberal education, then, appears to us to be indispensable. Acquaintance with the noble writers of ancient Greece and Rome, familiarity with the admirable literature of our own country, competent knowledge of the French and German languages, would, by general consent, form the groundwork: upon this would be reared the study of the natural or physical sciences—geography; mineralogy, and its twin sister, geology; meteorology; botany and vegetable physiology; zoology, comprising the natural history of man, and palæontology; physics and chemistry; and then of ethics and mental philosophy. These constitute the initiatory, the really indispensable preparatory studies of the future practitioner of medicine.

So complete a course of elementary education, we are aware, has, as yet, been but vaguely indicated among us as necessary; rightly pursued, however, it is not only the best discipline for the mind, but is also, beyond all conception, attractive to the youthful understanding. There is no knowledge of which the growing intellect is so greedy as that which has the

qualities and relations of the objects of creation for its subject; neither is there any kind of information that is so aptly retained, that proves of greater use, or that is so truly ornamental, as this in after life. Languages, to the mass of boys, are unmitigated drudgery; but we have scarcely met with one who had not an eager wish to be informed on subjects which are wont to be characterised as falling within the domain of *science*, and too apt to be viewed as beyond the grasp of the young mind. The study of languages, merely as languages—as matters that bear upon syntax and prosody, orthography and orthoepy; or, at the best, upon poetry, and rhetoric, and philosophy—belongs to the matured, not to the waxing intellect; and schoolmen have shewn their want of practical knowledge in their unavailing attempts to interest children in that which can only be interesting to grown men. The whole system of elementary education pursued in this country wants remodelling; Greek and Latin, and a smattering of mathematics, are far, very far, from being all that a man requires in the business of life; for which education, if it have any meaning, ought to be, from first to last, a grand preparation.

We would have languages, then, held as altogether subordinate to the study of natural science; they should be regarded but as means to ends, and nowise as constituting in themselves the ends. What we would insist upon is, the most liberal elementary scientific education, as necessary to the medical practitioner in his capacity of guide to the community in their efforts to mitigate and remove causes inimical to health and longevity. The proficiency which a youth has made in the several branches of natural knowledge that have been indicated, say at 18 or 19 years of age, would become an admirable test of his fitness to enter

upon the study of the medical sciences, properly so called. If he had not now acquired the amount of information on the physical sciences that might be held requisite, and did not display a certain degree of general shrewdness and ability, he should not be held qualified for the medical profession. Still he would have lost no time; on the contrary, he would have laid in a stock of information of a kind that must be useful to him in every situation in life. The world of business, of the mechanical arts, of manufacturing industry, would still lie open to him; and there he could make the talents he possesses available to himself and useful to the community.

A preliminary examination, in general letters and the physical sciences, of the young man who thinks of dedicating himself to medicine, we regard as absolutely necessary to securing the greatest amount of good that can possibly spring from any legislative enactment in reference to the medical profession: we, indeed, hold all the laws that can be made upon the subject as subordinate to this—the securing to the community highly educated men.

In our next we shall treat of medical education properly so called, and of the means of conducting it advantageously.

LONG ATTENDANCE OF MEDICAL MEN AT SESSIONS AND ASSIZES.

To the Editor of the Medical Gazette.

SIR,

I AM induced to make the following observations, in the hope that you, who are desirous of rendering every assistance to the profession, will enforce them on the minds of your readers, so that, by a combination of testimony, which without doubt will be added, the grievance may command the attention of those who have the power to remedy the evil.

The attendance of medical men as witnesses, at the sessions or assizes, for an indefinite time, is a grievance sorely felt by those who happen to reside at a

considerable distance from their county town, where such sessions or assizes are held. It is right and proper that nothing be done to hinder or defeat the full exercise of justice; but, on the other hand, nothing ought to be done which may in any way interfere with the consecutive treatment of disease; as ignorance of a case in reference to its history, peculiarities, medical means employed, &c. might endanger the life of the patient. We all know how anxious the public shew themselves to secure the attendance of that medical man in whom they place confidence; this anxiety is reasonable, and it were not too much to ask at the hands of the legislature for some arrangement to be made with the Judges which should secure the attendance of medical men, as witnesses in their professional capacity, at one specific time, that time not exceeding one day. Barristers and solicitors, who are in their element and at their post in an Assize Court, are perfectly reckless of the time of medical men, whose business, however, is suffering by their absence, and whose patients can never be persuaded that they are not neglected, when they know their attendants engaged in what they often think the more profitable occupation of attending in courts of justice.—I remain,

Yours most respectfully,

JOHN GRANTHAM.

Crayford, Kent, May 18th, 1844.

ROYAL MEDICAL & CHIRURGICAL SOCIETY.

Tuesday, May 14, 1844.

THE PRESIDENT IN THE CHAIR.

Case of a Tumor in the Right Hypochondrium, occurring after Injury from which a large quantity of fluid resembling bile was repeatedly withdrawn by the operation of tapping. By WM. R. BARLOW, Esq. of Writtle, Essex. [Communicated by EDWARD STANLEY, Esq. President.]

THE patient, a thatcher, set. 54, injured himself August 28th, 1843, by lifting a heavy ladder, and complained of so much pain in the region of the liver, that the author apprehended a rupture of that organ. He was very faint, in a cold perspiration, and the pulse scarcely to be felt. He was bled and purged. On the second day it was observed that the evacuations were white, and without bile, while the urine was dark,

as in jaundice. As the pain in the region of the liver continued, the bleeding was repeated at different times; he was put upon mercurials, and had a blister applied over the right hypochondrium. On the 15th September, a swelling of the size of a walnut was perceived over the seat of the liver; and this gradually enlarged till it had acquired, on the 9th of October, so large a size, and distressed him so much from its distension, that it was considered proper to tap it. Seven quarts of fluid were drawn off, and he obtained instant relief. This fluid, from its colour and taste, appeared to be pure bile. The swelling gradually enlarged again, and it was necessary to repeat the operation of tapping on the 21st of the month, when six and a half quarts were withdrawn. Upon analysis, the fluid was found to consist almost entirely of pure bile. After this he was tapped four different times, when similar quantities of fluid were withdrawn. On the last occasion, which was on the 26th Nov., only three pints escaped, and the swelling was not emptied; and he suffered considerable pain. On the following day bile appeared in his stools, and the urine was lighter coloured. The swelling was also much reduced in size, and it gradually subsided after this date. On the 4th February, 1844, he was quite recovered, and able to walk eight or ten miles. The author concluded with shortly stating several of the most interesting questions connected with the case, and proposing them to the attention of the society.

A desultory conversation, rather than set discussion, ensued. Dr. Copland took occasion to compliment the author on the very able manner in which his case was drawn up, and proposed it as a model—succinct, but embracing every point of necessary detail. Nothing but conjecture could be hazarded as to the real nature of the case. He viewed it, however, as one eminently calculated to show that injuries of apparently the most serious character were capable of being repaired by the powers of nature, if these were aided and not injudiciously interfered with. Upon this subject he had lately been engaged in making researches, and was surprised to find that so many instances of recovery after the most serious injuries had been recorded.

The President referred to the cases detailed in the early period of the session, in which considerable collections of an urinous fluid had occurred; apparently behind the peritoneum, and conceived that in all probability the collection of bilious fluid in this case of Mr. Barlow's was behind the peritoneum.

Mr. Arnott thought it very possible that the gall-bladder, greatly distended, might have been the sac that contained the bilious

fluid in this case. Cases of the kind had occurred, and he thought that in this instance there were grounds enough to justify its reference to the same head.

The President indicated the Memoirs of the French Royal Academy of Surgery as the collection in which the cases alluded to by Mr. Arnott were contained.

Mr. Hawkins did not see the necessity for supposing that the collection in Mr. Barlow's case was behind the peritoneum. It might have been within the bag of the peritoneum, and been circumscribed by adhesion. He considered it was by no means certain that the liver could not be ruptured, and the patient recover. In his own experience he had known an individual survive this accident so long, that nature had made the attempt to repair the injury, and the process of reparation had proceeded so far as to unite the lacerated portions. He alluded to a case of Mr. Prior's, recorded, he believed, in the Society's Transactions, where tapping had been repeatedly had recourse to, and which was probably made necessary by rupture of the liver.

Mr. Lloyd dissented from the idea of its being an enlarged gall-bladder, for in these instances the tapping had invariably been fatal.

The President observed that the exact nature of the original injury was somewhat puzzling, and certainly it was difficult to believe that the fluid was contained in the cavity of the peritoneum; indeed, he might mention that the irregular shape of the tumor, when he saw it, did not at all favour that view. It had been imagined, at the consultation held in the hospital, that some injury had been inflicted in the neighbourhood of the gall-ducts, that some lesion had taken place, and that the tumor might possibly be owing to subsequent inflammation and ulceration of these excretory ducts, which had led to the extravasation of bile into the cellular tissue outside the peritoneum. He again alluded to what he believed to be analogous cases of injury to the ureter, and consequent extravasation of urinous fluid into the cellular tissue exterior to the peritoneal cavity, which he had brought before the Society at the first meeting of the present session.

Mr. Streeter suggested that a direct rupture of any portion of the biliary ducts external to the cavity of the peritoneum would afford a ready explanation of the symptoms and circumstances of this case; for the absence of blood in the matter evacuated by tapping, together with the irregular shape of the tumor, and its slow formation, did not appear to him to countenance the idea of either rupture of the liver or extravasation within the peritoneum. In reference to Dr. Copland's remark, of the

powers of nature in effecting recovery in apparently hopeless accidents, he had, in the early part of this year, witnessed a striking instance in a young man whose horse fell with him while hunting. He was seriously injured on the left side of the abdomen, and the most alarming symptoms of internal laceration supervened, and yet he recovered. Two points of treatment he held essentially necessary for a successful result—the not giving food or any liquid for many hours after the accident, and the early administration of opium to stop the peristaltic action of the bowels, and thereby keep the injured parts at rest so as to favour to the utmost the formation of circumscript adhesions.

A Fellow of the Society thought, from the entire absence of bile that was observed immediately after the accident, and its re-appearance immediately after the severe and unexpected attack of pain that succeeded the last tapping, that it might fairly be inferred that some obstruction to the passage of the bile into the intestine had at that time been suddenly removed.

Table of the Cases of Strangulated Hernia treated in St George's Hospital in 1842 and 1843; to which have been added the details of some of the interesting cases, and the post-mortem examinations: with observations. By FRANCIS HEWETT, Curator of St. George's Pathological Museum.

The author began by giving a statistical account of thirty-four cases operated upon for strangulated hernia. The result of these operations was twenty-five recoveries and nine deaths. The sac was opened in every case; and in six cases a portion of omentum was removed. Five of these cases recovered, and one died of disease of the brain a few hours after the operation.

The author then gave, at full length, some of the cases which presented marked points of interest, and the post-mortem examination. Among the cases may be noticed Case 2, in which the gut, after having been strangulated for seven days, was, by the taxis, reduced with the sac. The symptoms of strangulation continued; the hernia fortunately reappeared in the groin during a fit of vomiting; the operation was performed, and the patient was discharged from the hospital eighteen days afterwards.

Reference was then made to four cases, in all of which the gut was enveloped by a complete sac, with a narrow neck, formed by the omentum. In relation to those interesting subjects, some quotations were given from Sir A. Cooper's and Mr. Lawrence's works, proving how very rarely these cases are met with. The author then proceeded to make some detailed observations on these omental cases, and on their

formation, which he referred to three principal varieties. In three of the cases the hernial and omental sacs were more or less extensively united to each other. In the fourth case the omental sac was lying loose in the cavity of the hernial sac. Large quantities of adipose tissue were, he said, sometimes deposited in the folds of the omentum, forming the second sac; and he referred here to one of the cases, in which the walls of the omental sac were more than an inch thick, as shown by the preparation exhibited at the meeting. The neck of these omental sacs, the author remarked, sometimes becomes the sole cause of the stricture: of this a well-marked example was given at full length. This circumstance was mentioned as an additional argument against the practice of reducing the hernia without opening the sac.

The author concluded his observations upon these cases, by adverting to the possibility of an alarming hæmorrhage taking place into the cavity of the abdomen, after the division of the neck of these omental sacs.

After some remarks upon the relative frequency of the strangulation of femoral herniæ, the numbers of which were given in the table, he made some observations on the "opening of the sac," which he, on various accounts, strongly advocated in the majority of cases. The paper was concluded by some remarks on the removal of the omentum, and the various modes of applying ligatures in these cases.

Mr. Lloyd advocated the propriety of not opening the sac, as it lessened the danger, and nearly reduced the operation to one of taxis. He had never known a patient die whose hernia had been reduced by this procedure. He preferred removing any portion of omentum, where such removal was necessary, by incision, and then securing the bleeding vessels, instead of applying a ligature, as recommended by Mr. Hewett in the paper. Why was the operation required? Because a stricture was already existing on the omentum. Would you, then, finish by making another? He considered it safer practice to separate any existing adhesions, and return the omentum into the abdomen, instead of allowing any part to remain after opening the sac. He also alluded to some instances of double sac which he had met with, and considered the occurrence as not uncommon in umbilical hernia.

— bore testimony to the accuracy with which the cases were narrated, and alluded to the difficulties which he, as a young surgeon, had experienced in performing the operation on a blacksmith, where he found a double sac and the inner sac formed the omentum adhering to the outer sac, which was formed by the peritoneum.

The President observed that he had lately noticed that hæmorrhage from the bowels frequently followed the reduction of a hernia by taxis. In one case it occurred to the extent of eight or ten ounces with the first motion. It did not seem a very improbable circumstance that the congested bowel should so relieve itself, but the symptom was new to him, although it might very possibly have been noticed by others; and, in reply to Mr. Lloyd, begged to assure him that hæmorrhoids had not been the occasion of fallacy in his observation.

Mr. Cæsar Hawkins had noticed the same circumstance.

The President then adjourned the Society till the 28th inst.

On the table of the Society Mr. Hewett exhibited the preparation of the very large scrotal hernia in which the sac was double. The whole of the outer peritoneal sac was lined with a thick and very adherent layer of omentum.

STATE OF THE PROFESSION IN THE PROVINCES.

To the Editor of the Medical Gazette.

SIR,

To those who, like myself, have the misfortune to reside at a distance from the great metropolis, nothing appears more remarkable than the want of knowledge prevailing among members of the medical profession in London, with respect to the mode of practice and general condition of their brethren in the provinces, especially of the surgeons (properly so called) practising in the large towns of England.

This deficiency of information is perpetually manifesting itself, both in the remarks of London journalists, and, still more obnoxiously, in the miserable attempts at medical legislation perpetrated from time to time by the Councils and governing bodies of the London Colleges.

Your leading article of last week forms one of many examples which might be cited in proof of my statement. Instead of its being true, for instance, that "all our extra-metropolitan surgeons, without exception," supply their patients with medicines, the facts are,—that a large proportion of the hospital surgeons in the provincial cities and towns, particularly in the *west* of England, do *not* practise pharmacy; that several of the leading surgeons have ceased even to practise midwifery; and that instances are not very rare in which great success has attended gentlemen who have commenced practice in large towns as "pure" surgeons. There is, in reality, a very respectable number of persons now practising out of the metropolis,

who have an equal right to the title of "pure surgeon" with the members of the Council of the Royal College; and the proportion of medical practitioners who devote themselves to the treatment of disease, disencumbered from the preparation and supply of medicines, is steadily increasing.

Far be it from me to utter a word in disparagement of that numerous, well-informed, and useful body of men, the country general practitioners; but I will not hesitate to assert, that there is a growing tendency among the more discerning portion of the community, to consult those surgeons who abstain from the practice of pharmacy.

Now it is highly unwise in the London College and its supporters to shut their eyes to notorious facts, or to look on with indifference, if not with jealous hostility, to this progressive change in the practice of provincial surgeons,—a change which may be hastened, or perhaps retarded, but which *cannot be prevented*.

After the foregoing observations, I shall not be accused of inconsistency in dissenting entirely from your condemnation of the conditions required by the Royal College of Surgeons in Ireland for admission to their fellowship. Those conditions I believe to be founded on reason, and on a just sense of what is due to the profession of a surgeon, considered separately from the trade of an apothecary.

How much clearer and more definite is the line of distinction between Fellows and Licentiates in the Dublin College, than that between Fellows and Members in London! In the latter the distinction is a mere badge of metropolitan patronage; in the former it is a living reality, the maintenance of which I hold inseparable from the maintenance of the honour and dignity of the profession. Had the London College acted on the same high and liberal principles—had it taken up a position in advance of public opinion, instead of being forced, as it will be, by pressure from without, to abandon its hold on obsolete notions and customs, how firmly would it have stood in professional estimation!

As matters *now* are, it is neither surprising that a strong feeling in favour of the Irish College should exist among provincial surgeons; nor is it at all improbable, that the admission of several English "pures" to the fellowship in Ireland may sharpen the perceptions of certain London gentlemen, whose ideal standard of professional superiority is measured by a five mile radius from the General Post Office.

Should this communication be honoured with insertion in the *MEDICAL GAZETTE*, I may perhaps presume to offer a few suggestions on the course which, as it appears to me, the London College might adopt to rec-

tify the errors in its new charter, and to set itself right with the profession in the country.

I am, sir,
Your obedient servant,
A PROVINCIAL SURGEON.

May 10, 1844.

["Licet omnibus," &c. as usual. We are only anxious to collect and to represent the true feelings of the majority of the profession, believing that out of the information thus obtained, thus diffused, good must result. We shall wait impatiently for an explanation, in the promised suggestions, of more than one part of the above letter.—Ed.]

THEORY OF MENSTRUATION.

"BEWARE the redding straik!" say the Scotch; that is, let him look to himself who attempts to compose a difference between two combatants. We were so much pleased with our task of raising up what we regarded as neglected genius and originality in Dr. Power, in our last number, that we are accused, by an esteemed correspondent, of having been less than just to another very deserving man, Dr. Robert Lee. We, however, never dreamed of questioning Dr. Lee's merits as having been the first to bring anatomical fact to substantiate Dr. Power's ingenious statements. We held this as unquestionable. Our correspondent says: "However well founded any view may be, still, if based only on analogy or indirect facts, it remains a mere hypothesis until direct observation of conclusive facts steps in to give it scientific value, and raise it to the dignity of a theory. Whatever credit, therefore, was due to Dr. Power, all scientific men must admit that *the theory of menstruation was not established, as it now meets us*, until the collection of observations on the condition of the ovary in females who happened to die during menstruation, was laid before the public, in 1833, by Dr. Robert Lee. The only fact wanting in Dr. Lee's observations, which still remains a desideratum, and is likely to remain so, is the detection of the ovum discharged from the ruptured Graafian follicle of the human female. As far as analogy from observations on the mammifera is admissible, however, this ultimate fact has lately been supplied by Prof. Bischoff, of Giessen, in his memoir entitled, *Beweis der von der Begattung unabhängigen priodischen Reifung und Loslösung der Eier der Säugethiere und des Menschen*, 4to. Giessen, 1844." In admitting this to be so, we trust that Dr. Power will not think we detract in any way from his merits; and in saying that we look upon the quality of mind which led Dr. Power to connect, with the familiar phenomenon of menstruation, the periodic maturation and detachment of an ovum, as of the highest and rarest order, we trust that

Dr. Lee will not imagine we abate one jot from his deserts in having been, as we have said, the first to search for, with the purpose of demonstrating, the connection which previously had been indicated, and advocated as an induction from admitted data, by Dr. Power. And here we wish this question to rest. The relative *share* which Dr. Power and Dr. Lee had in the matter is perfectly obvious. Different minds will estimate the relative *merits* of these inquirers differently. This is mere matter of opinion, and has no connection with the facts.—Ed.

A REMARKABLE ABORTION.

By DR. BUNDE, of Fredrikssund.

THE infant, a boy, was born with all the small intestines spread over his belly. It appeared that the thin membrane which had encompassed them like a sac, (a prolongation of the extended peritoneum) had been torn during delivery. The umbilical opening, whence the intestine issued, was the size of a shilling, and as several of the bowels were adhering to it, they could not be replaced. The child lived twenty-eight hours. On dissection it was discovered that there was no room for the bowels in the abdomen, because all the other organs were preternaturally large. The portion of the navel-string which had passed through the sac was very thin, but near the placenta it was an inch thick.—*Oppenheim's Zeitschrift*, Feb. 1844. p. 254.

IN Oppenheim's Zeitschrift, for October 1843, four cases are detailed where the lungs of still-born children floated in water; which would tend in some degree to invalidate the hydrostatic test.

ON THE LONG ISSUE OF THE SCALP IN DISEASES OF THE BRAIN.

MANY of our readers will recollect an excellent paper of Dr. Wallis, of Bristol, in the last volume of the Provincial Medical Association's Transactions, upon the above subject. In the number for 24th April, of the Provincial Medical and Surgical Journal, he makes some further remarks on the practice, and gives two remarkable cases in illustration of its power. Mrs. M., aged 40, after having suffered from severe pains in the head for 5 or 6 months, took to her bed. She was bled, purged, &c. but in spite of all, drowsiness and torpor succeeded. The head was shaved and covered with a blister, and ten grains of calomel every six hours were ordered. No improvement the next two following days; on the third night after, she was convulsed, and the right arm and leg became affected with spasmodic twitches. An incision seven inches long was now made in the course of the sagittal suture; the pa-

tient was insensible, and took no notice of the procedure; a thick roll of lint soaked in spirits of turpentine was placed in the wound. No farther convulsive attack; less tossing of the left limbs: a blister 16 inches long and 4 wide, was applied along the spine. The mouth became sore from mercury. By and by a double row of peas replaced the dossils of lint, and the patient made a perfect recovery. 12 months after this alarming attack she is well, and entirely free from her old headaches. The other case is one of hydrocephalus, in a boy 13 years of age, which seemed desperate, but also did well under the influence of the long issue of the scalp (7 inches) and a blister along the spine.

CASE OF INTUSSUSCEPTIO.

M. STAAL, a military surgeon in Stagelsøe, has recorded a curious case of intussusceptio, where the patient, after stercoraceous vomiting, was completely relieved by an injection of nearly four grains of extract of belladonna in gruel. This produced narcotic symptoms and speedy fecal discharge. The patient recovered in two days.—*Oppenheim's Zeitschrift*, Feb. 1844, p. 258.

KING'S COLLEGE.

DR. FERGUSON has resigned his professorship. His associate, Dr. Arthur Farre, will probably be constituted sole professor in the department of Midwifery.

Dr. Watson has been elected a member of the Council of the same institution, in the room of the late Sir Henry Hallford.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

Gentlemen admitted Members, May 17.—W. E. Stuart.—W. T. Hardern.—W. Cumming.—W. Wallford.—B. T. Lowne.—W. H. Thoreau.—F. J. Lilley.—T. P. Powell.—H. M. Gruggen.—J. Bomford.

APOTHECARIES' HALL.

Gentlemen who have obtained certificates, May 16.—C. Hall, Peatling Magna, Leicester.—H. M. Gruggen, Chichester.—T. Humphreys, Anglesea.—W. Earengay, Plymouth.—E. Dewes, Coventry.—J. Hakes.—W. B. Kellock, Totneas, Devon.—A. W. Williams, Shrewsbury.

BOOKS RECEIVED FOR REVIEW.

On Dysmenorrhœa, and other Uterine Affections. By Edward Rigby, M.D.

On the Nature and Treatment of some of the more important Diseases, Medical and Surgical, including the principal Diseases of the Eye. By John Charles Hall, M.D. &c.

On the Nature and Treatment of Deafness and Diseases of the Ear; and the

Treatment of the Deaf and Dumb. By William Dufton, M.R.C.S.

Mesmerism and its Opponents; with a Narrative of Cases. By George Sandby, M.A. Vicar of Flixton, Suffolk.

TO CORRESPONDENTS.

We have a letter from a physician practising in Leeds, stating that a respectable tradesman of that town had lately died under the operation of the water-cure (*gy. water-death*) at Ilkley, and calling upon Dr. Hobson, Dr. Drennan, and Mr. Garlick, who were present at the necropsy, to communicate the facts connected with the case which had come under their notice.

M. B. appears to set ——— right on the true spinal system, but he gives no new information on the subject. We should like to send ——— M. B.'s letter, if he would favour us with his address. To publish it in the *GAZETTE* would bring ——— on us again.

We cannot see anything new or peculiarly interesting in the "Two Cases of Puerperal Fever." The disease in the second instance was certainly carried by the practitioner to the patient.

The "Case of Pneumonia with vomiting," offers no point of peculiar interest.

MORTALITY OF THE METROPOLIS.

Deaths from all causes registered in the week ending Saturday, May 11.

Dropsy, Cancer, Diseases of Uncertain Seat	71
Diseases of the Brain, Nerves, and Senses..	165
Diseases of Lungs and Organs of Respiration	241
Diseases of the Heart and Blood-vessels	35
Diseases of Stomach, Organs of Digestion, &c.	54

WILSON & OSLEY, 57, Skinner Street, London.

THE LONDON MEDICAL GAZETTE,

BRING A
WEEKLY JOURNAL

OF

Medicine and the Collateral Sciences.

FRIDAY, MAY 31, 1844.

SUBSTANCE
OF
A CLINICAL LECTURE,

Delivered at St. George's Hospital,

By CHAS. HAWKINS, Esq.

Surgeon to St. George's Hospital.

1. *On a Case of Ossific Formations in Muscles.*
2. *On Contraction of the Fingers of both Hands.*
3. *On Suppurating Bursæ in the Sole of the Foot.*

THE natural and new formed tissues of the body are capable of undergoing a transformation from one state to another; and a very common order in which such a change may be observed is this:—Some common cellular membrane may be subjected to pressure or other influence, by which the tissue is first condensed and smoothed into a cyst, such as you can see in this preparation resembling a serous membrane, and secreting fluid. In the course of time, the cyst, by inflammation, may be thickened still more, and altered sufficiently to resemble a completely fibrous texture, still preserving, perhaps, its smooth secreting surface; and then, finally, as you see here, the fibrous texture may be converted in part, or wholly, into bone. When there is an excess of earthy matter in the system, you have evidence of the fact sometimes in the formation of exostoses, or excrescences from the bones; but you will also see it in the change of the softer fibrous tissues into bone; sometimes in new formations, as in this serous cyst from the liver, or this bony tumor which I removed from the skin, and which appears to have been a sebaceous encysted tumor originally; sometimes also in tendons and ligaments. Look, for instance, at this long process, formed by what had been the ten-

don of the *psoas magnus*, where it is attached to the trochanter minor; and I remember an instance in which numerous portions of the vasti muscles underwent this conversion, and formed a great mass of bony processes surrounding the femur. Here, again, the ligaments of the spine have been changed into bone, and have rendered the vertebræ quite immoveable on each other. These tissues are often thus changed in old persons, in whom obscure pains like rheumatism or lumbago have been known to precede the change, and seem to shew its inflammatory nature;—and I may observe, that it is remarkable that elderly people should be liable to the change in question, since, as you know, their bones have a diminution rather than an excess of earthy deposit in them. Besides the tendons and ligaments, the natural fibrous membranes also undergo the same transformation, such as this large mass in the pericardium, or this bony deposit in the dura mater, the falx being its common situation, and epilepsy being sometimes the result.

It would seem that ossification of the fibrous texture of muscles may be the result of simple inflammation; for there was an account published some years ago of such a change in many recruits in the Prussian army, in consequence of the pressure and irritation induced by first carrying the musket. The surgeon who wrote this account says that he found it in as many as eighteen out of 600; and that a swelling of the deltoid and pectoral muscles in front of the shoulder took place, bone being deposited so as to require removal by operation; and that the pieces of bone were from $2\frac{1}{2}$ to 7 inches in length. It is singular, however, that such a circumstance should be thus common in one country only, and not be found in our own army, or in other armies; for I suppose the nature of the musket, and the mode of handling and carrying it, must be nearly alike in all countries.

But, in the next place, tendons, and liga-

ments, and muscles, have been occasionally known to be ossified in young persons as a remarkable form of disease. You are probably familiar with one instance, as it is found in many works in your hands, such as Cooper's Surgical Dictionary, which occurred in a boy who fell under Mr. Abernethy's observation, in whom the least blow or other injury would cause an exostosis, or an ossification of some muscle or ligament, till he was perfectly crippled. I recommend you also to look at the College of Surgeons, at the skeleton of a Mr. Jeffs, who lived for many years with this tendency, so that at 39 years of age, when he died, a vast number of such masses had formed, and ankylosed and fixed almost every joint or moveable part of his body.

There is, as you know, a man in the hospital who has ossification, or a tendency to ossification, in many parts of the body, and whom some of you have seen for nearly the whole of the last year; and as he came here at the beginning of his complaint, so that we know more of the history than in the two remarkable cases I have before alluded to, and the case is altogether very singular, I will draw your attention to this subject to-day. First of all, as the notes of the case are scattered in more than one book, and are from the pen of several successive clinical clerks, and as many of you have only seen the latter part of the case, I will give you an abstract of the series of parts affected, and the changes they have undergone.

George Brown, a groom, æt. 22, was admitted June 14th, 1843, with swellings in the lumbar and dorsal regions, which commenced a week before with violent pain, which has since subsided, but still exists when he moves himself, and which began just after he got wet through. One swelling is situated about the transverse processes of two or three of the lumbar vertebrae, on the right side, about four inches long, and an inch and a half wide, pushing the long muscles outwards; it is of very firm texture, apparently bony, and gives no pain on pressure. There is another enlargement, of rather greater breadth, in the left dorsal region, which is, however, not so hard as that in the loins; it gives some pain on pressure. It covers the three upper ribs close to the spine, and does not move with the scapula; and it appears to be covered by the rhomboid muscles. He says he was always high-backed, but perceived no swelling till the week before his admission. On the 19th, five days afterwards, neither prominence was so large; and July 10th, the upper swelling had subsided, and the lower also partly, so that the transverse processes could be felt, but with hard bone added to them, such as you can now feel; but the note of the same date, July 10th, says, ano-

ther large prominence appeared the day before yesterday beneath the *left* axilla, at the anterior margin of the latissimus dorsi, and apparently situated on the serratus magnus, and on the 17th a similar tumor shewed itself in the same situation on the *right* side, and near it another hard painful swelling shewed itself yesterday, situated apparently below or in the pectoralis major of the right side, from its lower border to an inch below the right nipple.

On the 21st the scapuli on the left side were observed to be hardened and stiffened with slight swelling.

On the 31st the tumors on the right side were nearly gone, but the swelling over the dorsal vertebrae was again more prominent and elastic, and another swelling was found at the side of the lumbar vertebrae of the left side, exactly opposite the one present when he was admitted. By the 23d of August all the swelling had nearly disappeared, and he left the hospital on Sept. 6th, very well in health, and, as we hoped, cured, but holding himself very stiffly, and unable to bend the spine in bowing, which movement was performed only at the acetabulum.

But he was obliged to be readmitted on the 25th of October, in consequence of a recurrence of his complaint, the swellings being now more numerous and more prominent than before; and the notes at this date say—On readmission it appeared that he had continued his medicines most of the time he was an out-patient; but the pain and swellings had soon returned without fresh cold. The lower part of the sternomastoid muscle was very hard and inflexible for about three or four inches: the original swelling of the left side of the loins was apparently ossified: there was a good deal of swelling between the left scapula and the spinous processes of the vertebrae, a little lower than most of the tumor which he had on the left shoulder on his first admission, and in the centre was a small mass of osseous substance extending laterally as if in the rhomboid muscle, and moveable: under the angle of the right scapula, raising it outwards and a good deal impeding its movements, was a swelling of the same part, apparently (in part at least) of the serratus, which had existed when he was in before, and on one rib below this swelling, and fixed to the rib, was a small exostosis: the scapuli were still hard: all these swellings were painful and somewhat tender: he did not seem out of health, and was fat.

We pass on for about a month to Nov. 30th, at which time it is said, the soft swellings of the sternomastoid, scapuli, and serrati, and rhomboid muscles, have all lessened; but his movements are much cramped, the spine being very stiff, and the right arm cannot be lifted or moved. The left arm

moves easily, but the bony mass behind is now full two inches long, and is raised outwards by the scapula when the arm is depressed; it cracks by touching the base of the scapula. As this ossified mass was fast increasing, and was becoming fixed to the spine, I removed it by operation Nov. 23d. It was situated between the trapezius and rhomboid muscles, and was intimately associated with both, having the fibres inserted, as you perceive in the preparation, just as they might be into the periosteum of a natural bone. One end was smooth, from playing on the edge of the scapula; the other was fixed to, and partly ossified with the spinous process of the sixth or seventh dorsal vertebra. It was, as you see, about three inches long, of an hour-glass shape; the broadest part being about an inch in breadth. Most of it was firm bone, a little portion was cartilaginous, and the narrowest part was partly moveable;—it was in shape not unlike the two phalanges of the thumb joined together. Several vessels of large size were divided, and hæmorrhage took place afterwards to a great extent, so that he was very much reduced by it. The wound was slow in healing, but during the time nothing fresh took place; and on December 18th it is noted that the deposits were much diminished, except at the angles of the ribs, in the left scapula, and on either side of the lumbar vertebrae.

I carry you on, next, to February 2d of the present year, when our notes say, he perceived a swelling coming on last evening under the right pectoral muscle, where it is attached to the ribs; it is of an oval shape, measuring in length about three inches, in breadth two and a half; it is soft, but immoveable. You saw in this, and in others of recent formation, the mode in which the swelling made progress, without ossifying: coming quickly, and at first soft; the next day it was harder and larger; and on the 4th it was from four to five inches long, by three broad; and the pectoralis minor was now implicated. On the 12th it was softer and flatter below, but was spreading above. On the 18th it was still extending upwards to the insertion of the pectoral muscles. On the 19th the swelling was less prominent, but there was great hardness, and the muscle was knotty and irregular. By the 24th the skin and cellular tissue were again moveable over the muscle, the hardness and knottiness of which were still noted; and on March 1st, the notes say, there was no trace of the swelling.

On the 4th of March, however, we find there is now a large swelling about the size of a goose's egg, just below the inferior angle of the left scapula, fixed, but apparently connected with the serratus; soft-but firm; that is, not bony it crepitates on pressure: this

was around a small exostosis which had formed since the same part swelled in July last. There was also observed on this day a swelling about the ligamentum nuchæ, four or five inches long, and very firm, and hard, and affecting all the muscles inserted in the occiput, besides the trapezius, being nearly two inches thick, and of some breadth.

On March 7th, the swelling below the scapula had increased, it being double the size it was on the 4th, and now as large as a seucer; the crepitation is gone, and it is much harder, and appears fixed: two days after this a cast was taken, which shows how very large the swelling then was, nor has it gone away at the present time (May 21st), though it began to lessen on the 13th March.

We pass on next to the 29th March, when a fresh swelling took place in the left pectoral muscle at its axillary border; but this lessened by April 2d. On April 12th, another formed of considerable magnitude under the latissimus dorsi of the right side, a little more backward than the former, which seemed to be in the serratus, and which was softer on the 15th. On this day, the pectoral muscle of the left side being smaller, was found to have a hard substance in it, which I thought would prove to be osseous, but it seems to be softening a little now. Since this time no fresh tumor has been noticed.

Such is a connected history of this singular case, and you can see the state the patient is now left in: very stiff from ossification of the lumbar vertebrae, and hardness of the muscles of the neck, and unable to use the shoulders freely on either side, but particularly on the left, owing to swelling under the angle of the scapula in the serratus, and from the almost ossified state of the tendon of the pectoralis major, which is moveable in two portions where the tendon revolves at its insertion, so the lower fibres may reach the top of the tendon of the reverse; he has also a small exostosis on a rib on each side, which does not appear to occasion any trouble, and is not increasing.

The next question is, of what nature is this disease? It is evidently of constitutional origin, since it has lasted so long, and has shown itself in so many different parts of the body. It came on, as you have heard, from the patient's getting wet, and apparently, therefore, is allied to rheumatism, though thousands of cases of rheumatism take place without such consequences as are here seen. The patient, however, has none of the usual symptoms of rheumatic disease, nor has he ever had any on former occasions; there is no deposit of lithates in the urine, no acid secretion from the skin. On one occasion the water was even alkaline; but this was at a time when he was reduced by illness, and had taken alkaline purgatives. It directly

afterwards became healthy, and has been so whenever it has been examined—acid, but not in excess, and without sediment of any kind. I may observe, too, that the ossific deposit is not composed of carbonate of lime, as many earthy concretions are, but of phosphate and carbonate, as in true bone, with cancelli, and an outer shell, and periosteum, and cartilage, and with all the signs of true bone, even when examined under the microscope. There is nothing apparently wrong in any function; the limbs act healthily, the appetite is good, and the pulse and tongue shew no sign of disease; the only circumstance which you can observe unusual, is a morbid greasiness of the skin; but the perspiration goes on naturally, and a copious secretion from the sebaceous follicles can have no influence on the system, and is not at all uncommon.

Nor has any thing been satisfactorily made out in former cases in which a tendency to ossific deposit has been observed. It has been known, indeed, to occur in more than one of the same family. I was consulted, for instance, very lately, for a young lady, who had an immense malignant tumor of the thigh-bone, and her sister also has an exostosis of apparently an innocent nature. Mr. Stanley met with a man in St. Bartholomew's, with exostosis, several of whose relations had also bony tumors, and Boyer and others have occasionally seen the same thing.

A man had his thigh amputated in this hospital, for what seems to me, judging from the preparation, to have been an innocent osteosarcomatous tumor, and five months afterwards the man had pulmonary symptoms, of which he died; and you may see in the museum of the College of Surgeons that besides numerous ossific deposits in the pleura, or rather, I suppose, in the cellular tissue behind it, the lungs also have great masses of bone in them, occupying a third at least of their bulk. Some bone has also been found in an absorbent gland after the operation for a tumor of a bone; but these circumstances are obviously incidental coincidences, evidence of excess of phosphate of lime from want of assimilation, and not evidence of return of disease of a malignant nature, like medullary tubercles in the lungs after the removal of a cancerous tumor. Our patient is rather pale and pasty in complexion, but shows no sign of any definite derangement of system.

Neither do the local changes enlighten us as to the nature of the malady: it is obviously inflammatory, indeed, from the pain and swelling and tenderness, and secretion of serum and lymph, but I cannot say why the muscles inflame, nor why the common results of inflammation are modified so that bone is formed in the cellular tissue of the muscles, and of the surface of the ribs.

If, then, I cannot assign any cause for this curious succession of inflammations, I am very little likely to be able to tell you what you are to do for a similar case if one happened to present itself to you. Let me mention, however, to you in abstract what has been done in this case, and what has been the influence of remedies, as far as we have observed them.

First, then, with regard to local remedies, I have repeatedly used a blister over the affected part, because this counterirritant has invariably done good, reducing the swelling and lessening the pain. I have also used a solution of iodine and iodide of potassium with a little advantage, but never with so much as seemed to be derived from blisters. Cold also relieves the inflammatory pain to some degree.

When he was first admitted, as the disease came on after cold, and thus seemed to resemble a rheumatic seizure, though with singular swellings, I gave the patient colchicum, which he took from June 19th to the 30th, with some effect, as it seemed, on the size of the swellings, and with relief of pain, but no effect, perhaps, in preventing fresh tumors. I resumed the colchicum, however, when the swellings began again on July 10th; but as they continued to form, I changed this medicine for the iodide of potassium on the 21st, beginning with five grains, and increasing it to seven grains, thrice in the day; and under its use, with an alteration of diet for the better, the disease seemed to yield pretty steadily. On August 14th I added sarsaparilla to the iodide, and he went out, as we have seen, Sept. 6th, apparently cured. But although he went on with these medicines some time longer, as he says, the disease returned in spite of them. On his readmission, therefore, on Oct. 25th, I tried him with a new plan, and put him on the use of mercury; he took two grains of calomel, with a quarter of a grain of opium, twice a day, which he continued from that date to Nov. 17th, about three weeks, his mouth being made moderately sore by it. Under this course all the swellings were nearly absorbed, at first rather rapidly, and afterwards more slowly; but nevertheless the mass of new bone in the shoulder went on increasing in size, and as he would plainly have been quite crippled if it had joined the scapula, with which it was in contact, as it had fixed itself to the spine, I thought myself obliged to remove the tumor. We have seen that serious hemorrhage resulted from the operation, from the effects of which he was a long time in recovering; he, indeed, required much support to restore him to nearly the same strength as before. Whether it was owing to the loss of blood or not, I cannot say, but no relapse took place till Feb. 2d, when

the local remedy of two blisters was followed by an attack of erysipelas, which lasted a considerable time, beginning on the 22d of February. This was succeeded by the formation of an abscess in the axilla of some size, originating in a gland, and during the whole of this time numerous tumors were continuing to form in the muscles; so that the lowering of the system by these attacks did not prevent them, as it seemed not improbable that the loss of blood might previously have done. On the 6th of April, he was again sufficiently recovered to bear some specific plan of treatment, and I gave him phosphoric acid, which he had taken once before for a few days, before I was obliged to operate. He began with half a drachm, and now takes a drachm of the diluted phosphoric acid three times daily, and has continued it till the present time (May 21st.) My reason for this is theoretical only, namely, that the phosphate of lime, which he seems to have in excess, is an insoluble salt, while the super-phosphate is soluble; and it might, therefore, be supposed that if the acid could act in this way on the salt, the deposits might be prevented. This is, no doubt, a very vague kind of theory, but yet it is certain that during the use of the acid, with the exception of one tumor on the 12th April, a few days after he began it, he has had no fresh inflammation, and all that were forming when he commenced its use have much diminished. I may be asked, as the disease is obviously inflammatory in some measure, why depletion has not been employed? It has appeared to me, however, that the pulse never indicated this practice, and I do not think his being fatter or thinner, stronger or weaker, on low diet or good diet, has in any way prevented or accelerated the progress of the disease. It is altogether so very singular a case that although you may never see another of the same kind, and it does not, therefore, form so practical a subject as some others, I have nevertheless thought that placing the whole of it at one view before you would not be uninteresting.

I will take you, in the next place, to another subject—a disease which does not affect muscles like the former, but is yet allied to it, inasmuch as tendons and fascia are implicated in the affection; the case is also not very common, though you may perhaps meet with it, and ought to know how to treat it. The case is this:—

William Kisby, æt. 39, a coachman, was admitted on the 17th of April, with contraction in a greater or less degree of all the fingers of both hands, but chiefly of the fore, ring, and little fingers of the left hand, and of the ring and little fingers of the right hand. The fascia in the palm of the hands

is very tense and hard, as also are the parts of the fascia leading down to the metacarpal bones, and then also those portions of the fascia which pass to the sides of the phalanges. There is no anchylosis of any of the joints, but there is partial dislocation of the second phalangeal joint of the ring finger of the right hand, which arises from the pressure of the fingers in their bent position against anything the man tries to grasp. The cutis in the contracted parts is much condensed and furrowed, and apparently thickened. Now the notes correctly describe the nature of the disease in this case; namely, that the contraction is in the palmar fascia, and not in the flexor tendons, though on first examining the hand you might easily suppose that the lines of hard substance, which start up when you try to extend the fingers, are the flexor tendons. In the Clinical Lectures which have been published as given by Dupuytren, you will find a very good account of this affection; he says he was the first person who discovered the real nature of this contraction, and mentions one case which he cured by operation after it had been pronounced incurable by Sir Astley Cooper. Dupuytren makes the same claim, indeed, with regard to most of the subjects he treats; but in this instance, at all events, he is probably correct in asserting that he first ascertained the cause of the contraction by dissection. It consists, then, of a slow contraction (with some inflammation probably, as there is sometimes pain in the affected part) of the portions of the fascia which separate from the annular ligament in the palm of the hand, and of the subdivisions of the fibrous mass which pass to the phalanges of the fingers, the tendons being only somewhat shortened by want of use for several years, and the skin being a little hardened and condensed, and intimately united with the fascia. Dupuytren says that it takes place in those persons who are subjected to laborious employments, in which some hard substance is constantly rubbed and pressed in the palms of their hands, and he instances coachmen, of whom our patient is one, as being one of the classes liable to it. I think, however, you will be able to find a few coachmen in London besides this man, and perhaps you will look in vain for another instance of this contraction among them. I have seen it, moreover, in several instances, in persons of a higher class of life, who have never, as far as I know, been subjected to the causes I have mentioned; so that I am not certain that the opinion of Dupuytren is correct; and I do not see very clearly why, if it were correct, the contraction should be confined, as it almost invariably is, to the ring and little fingers; nor why it should attack both hands as in this case (which is not, indeed, a common cir-

cumstance); for the two hands are very differently employed in his labours. This man had some little contraction of the fore-finger also, but it has nearly gone since he has been in the hospital, and it is unusual.

The remedy for this contraction is the division of the portions of fascia which are affected; and it would appear to be an effectual cure; at any rate it is so for a considerable time after the operation, and can easily be repeated if the contraction returns. I performed the operation, some years ago, on a patient in the hospital, and after two or three years I think the fingers were beginning to contract again slightly; the relapse was not, however, sufficient to require a second division, as it was no inconvenience to him, so that he has not come again to me. I have not been able to perform the operation for our patient yet, for he was unfortunately attacked, a few days after admission, with gouty inflammation, to which he is liable, in several joints successively, which has not yielded readily to medicine. He is now, however, tolerably well again, and I shall probably operate on the affected parts of one hand in a day or two, leaving the other till a future time, that I may not make him altogether helpless while he wears a splint, which must be kept on for a considerable time.

With regard to the mode of performing the operation, you are aware that, for contractions of tendons, we generally endeavour, at the present time, to perform a subcutaneous incision, so that no air may enter the divided parts to interfere with union by the first intention; and the parts having united to a certain degree, extension is then made, to separate the ends while the united substance is still soft. Now I have turned over in my mind the propriety of acting thus in the present case, but I am inclined to think I shall not do so. You know that the great risk of wounds and injuries about the plantar and palmar fascia is from confinement of matter, which is then made to pass along the tendons of the muscles, and thus they form very troublesome cases. Now in order to remove the contraction in this case, it will be necessary to make several cuts; the band of fascia must be divided in the palm before its separation to the two fingers; each finger must probably have another incision opposite to the joint with the metacarpal bone, and very likely smaller cuts must be made at the sides of each finger. To do this below the skin, which is inseparably joined to the fascia, must be at least very difficult, and not without risk of the digital arteries and nerves being injured; and then, as the extension on a hand splint must be considerable, I think it would be altogether impossible to escape suppuration in some of the several incisions. If the operation is done in this

manner, and matter does form, it is necessarily confined, and may do much harm. I think, then, I shall operate, as I have done before, by direct incisions through the skin and subjacent contracted portions of fascia. It is true there will thus be several suppurating wounds, a little lint being put between the edges of the incisions to prevent their union; but then, on the other hand, there will be no confinement of matter, and consequently no probability that the suppuration will extend itself beyond the small cuts themselves, which extension is much more dangerous than the open wounds can be. It does not appear that Dupuytren met with any mischief when he did the operation in this way; and when I have done it myself, there was no inflammation of any importance produced.

In the short time which remains, I will draw your attention to a case, of not much importance in itself you may think, but it is one which you will probably often witness, and which is somewhat peculiar in its nature, and would give you trouble if you are not aware of its precise nature.

Thomas Nicklin, *æt.* 43, was admitted last week, May 15th, with a sinus at the under part of the right heel, leading deeply down towards the under part of the os calcis; a probe passed along it does not strike on exposed bone. The skin and parts around the sinus are very much thickened; the surface of the cavity is pale and without granulations. It came from cold, sixteen or eighteen months ago, as a small hole in the skin, with discharge of matter. There are some other notes relating to his health, which I will not read to you, as they are irrelevant to the remarks I am going to make.

Now I believe that this has been, in reality, a case of suppuration in a bursa under a large corn; and, without being aware of it, you will easily fail to recognise such a case; and yet you see, by this man's abscess, which burst a year and a half ago, that there must be some reason for so small a cavity not healing in this time; and this reason is, the peculiar nature of the bursa, which is incapable of forming granulations; and here, as the orifice is larger than usual, you can see the inner surface, which is pale, and thin, and white. Such a bursa not unfrequently forms under a corn, to defend the ligaments and joints from its pressure, either in this situation, or under the ball of the great toe, or under the metacarpal joint of the little toe; and is liable to suppurate, and discharge by a small orifice, with a hard margin: on inserting a probe, you occasionally find that the ulceration has extended in the contrary direction also, and has destroyed the periosteum of the bone, or has even opened a joint, so

that bone is felt by the probe, which exfoliates, or the joint is ultimately quite ankylosed. A similar appearance is thus produced to what you can see in another patient admitted on the same day, with ankylosis of a part of the joint of the metacarpal bone of the great toe with the first phalanx, while dead bone is felt in both of the exposed surfaces.

What I have found it necessary to do, in such a case as this, is to enlarge the orifice, and if it is necessary, destroy the whole of the inner surface with strong nitric acid, inserted by means of a little sharpened piece of wood; then you will succeed in procuring a granulating surface, and you can afterwards apply common remedies—red precipitate, solution of caustic or copper, and so on. You should, at the same time, cut away as much of the thickened cuticle or corn as you can from around the opening. The nitric acid gives little pain to the bursal surface, and is quite effectual in general. If the cavity or sinus is close to bone, or to a joint, you must apply the caustic somewhat carefully, in order not to affect those parts; or if the bone is already denuded, the acid may be applied to its surface also, and, partly by its stimulant quality, and partly by its chemical action on the bone, this part will probably be absorbed, or become healthy and heal up. Two or three applications of the acid are, from this cause, sometimes necessary, in order to avoid the mischief endangered by the too free application of it in the first instance.

REPORT ON THE ROYAL MATERNITY CHARITY.

By F. H. RAMSBOTHAM, M.D.

(For the London Medical Gazette.)

[Continued from p. 258.]

DURING the year 1836, there were delivered in the Eastern District of the Royal Maternity Charity, under the superintendence of Dr. F. H. Ramsbotham,—

2268 women—Of which cases,

22 were twins—about one in every 103 cases: of these, in 4 both heads presented; in 15 the presentations were head and breech, or some part of the inferior extremities; in 2 both breech or some part of the inferior extremities; and in one head and shoulder. In 6 both the children were boys; in 9 both girls; and in 7 they were of different sexes.

1 was a triplet case, at full time; they were fine children, all born alive, two girls and a boy; two presented with the breech, one with the head.

1150 were males.

1142 were females.

2215 were presentations of some part of the head, of which

8 were face presentations—about one in every 286½ births; with two of these the funis prolapsed.

73 were presentations of the breech, or some part of the lower extremities—about one in every 32½ births; of these 19 were twins, and 2 were of the triplets.

4 were transverse presentations—one in every 573 births; all of the shoulder; all the women were delivered by "turning;" three of the children were born still.

In 4 the placenta was implanted entirely, and in 4 partially, over the os uteri—one in every 283½ cases. Three of the cases in which the placenta entirely covered the mouth of the womb were terminated by "turning;" in two the children were born living, and the women recovered; in one the child was extracted dead, and the woman died suddenly immediately after delivery. She was more than 40 years old, and it was her first child; there was excessive rigidity of the os uteri and other structures. When I saw her first, the os uteri was not dilated to a greater extent than the size of a shilling. I passed a catheter into the cavity by the edge of the placenta, and ruptured the membranes: the hæmorrhage did not materially abate, and in two hours I proceeded to deliver. I had great difficulty in introducing my hand and extracting the body. I was obliged, after the delivery of the trunk, to perforate the head behind the ear to enable it to pass; the placenta was immediately expelled, and although she had spoken cheerfully the minute before, she expired suddenly directly it was born. In the other case the placenta was expelled rapidly before the child by violent uterine action, and the child passed immediately after; it was born alive. It was at seven months.

Of the 4 partial presentations, one woman was delivered by turning the child, the head being at the os uteri. She had lost an immense quantity of blood; the child was dead. She went into a convulsion immediately after

delivery, but ultimately recovered perfectly. One case was a breech presentation, terminated by bringing down the feet, and delivering artificially; the child was born living; the woman did well. In the two other cases the head presented; in both the flooding ceased, or was very materially diminished, on the artificial rupture of the membranes, and both children were expelled by uterine action, living. One was at seven months.

3 were complicated with alarming accidental hæmorrhage before delivery, *not* the result of placental presentation—one in every 756 cases. In two of these cases the head presented; the hæmorrhage in both ceased, or was much lessened, on the membranes being ruptured; the women were delivered naturally, and both did well; one of the children was alive, the other still-born. In the other case the breech presented; the case was terminated by bringing down the feet; the child was born living, and the woman did well.

In 8 the placenta was retained within the uterus either by atony, or irregular contraction of the uterine fibres, or by morbid adhesion between the uterine and placental surfaces, requiring the introduction of the hand for its removal—one in every 283½ cases. Seven of these women recovered; the other died on the 17th day after delivery. A portion of the placenta was left within the uterus. It was removed by a gentleman not connected with the charity.

4 were complicated with alarming hæmorrhage after the natural expulsion of the placenta—one in every 567 cases. One of these patients died in an hour after delivery.

2 were delivered by the forceps—one in every 1134 cases; one was complicated with convulsions; the child was dead; the woman recovered. In the other case the child was born living, and the woman did well. They were both primary labours. There was no case of head presentation requiring craniotomy during this year.

1 was complicated with true puerperal convulsions; the fits came on when the head was in the pelvis. Bleeding relieved her considerably, but as the woman still continued insensible I delivered her by the forceps. She had no return of the fits after, but did not regain her consciousness for twelve

hours. She ultimately recovered perfectly. The child was dead.

In 2 premature labour was induced—one in every 1134 cases; they were both breech presentations, and both the children were still-born. In one case the labour was brought on solely by the ergot; she took the medicine for five days, every six hours. The child was putrid when expelled.

1 child was hydrocephalic; the head passed whole.

8 women died either within the puerperal month, or from puerperal causes—one in every 283½ cases; 7 only, however, from the effects of labour, for one sunk under confirmed phthisis of long standing a fortnight after delivery—one in every 324 cases.

2202 children were born living.

90 children were born still—one in about every 25½ births.

Of the Deaths,

1 was immediately after delivery, under a placental presentation.

1 from hæmorrhage, an hour after the natural expulsion of the placenta.

1 on the 17th day after delivery: there was an adherent placenta, which was disrupted and a portion left.

2 from peritonitis; both seven days after delivery.

2 from mania of a furious character; one seven, the other fourteen days after delivery.

1 from phthisis a fortnight after delivery.

Of the still-born children,

22 were premature.

6 were putrid at full time, or nearly so.

17 were presentations of the breech, or some part of the lower extremities, at full time, or nearly so.

3 were transverse presentations, at full time, or nearly so.

2 were delivered under placental presentations.

1 after violent accidental hæmorrhage.

1 under convulsions—a forceps case.

3 under very lingering labours.

3 were twins.

In 2 premature labour was induced.

With 6 the funis prolapsed by the side of the head.

1 was a face presentation.

1 was hydrocephalic.

In 2 the mothers had had many still-born children in succession.

In 4 the mothers had suffered some accident near their full time.

16 were at full time, not putrid, nor delivied by art, there being no evident external cause to account for the calamity.

CONTRIBUTIONS
TO THE
PHYSIOLOGY OF THE HUMAN
OVARY.

BY CHARLES RITCHIE, M.D. Glasgow.

[Continued from p. 256.]

19. The third general class of discharged ovisacs was distinguished by the secretion of an organized, yellow-coloured, brain-like, granular matter, and differed.

A. As the cerebriform matter was connected with ruptured ovisacs of (15) the first class, having transparent, pellicular coats, or with those of (16) the second class, having either their outer or inner coat thickened.

B. According as the granular substance was deposited external to the inner layer only, or to the two internal layers of the ovisac.

A. In menstruating females, and also during the first months of the gravid state, and sometimes even in the period of lactation, the ovaries were found occupied by one or more, and, at times, by five or six yellow bodies or cysts, the structure of which, especially in the more perfectly organized specimens, presented a striking resemblance to the convoluted, reddish-yellow surface of the brain, covered by its inner membranes, and painted with its scarlet coloured and dark vessels, and which, in the cases which admitted of it, had some resemblance, when it was examined by transmitted light, to the appearance presented by granules of adipose tissue. The coverings of the cysts were often, in delicate or in unhealthy females, or when their absorption was advanced, so attenuated as not to admit of demonstration (P. II., S. VII., 10), but in general they possessed the structure and appearance of the coats of the ovisac as these exist previous to the rupture, and in other instances they had undergone various degrees of that process of thickening by which the matured and discharged Graafian vesicles or ovisacs are transformed into white bodies.

In the cysts with thin transparent membranes, the inner surface was, with

some exceptions, where a membrane could not be detected (P. II. S. VII., 8), found lined by a delicate pellicle, which was often stained with blood, through which the yellow matter was visible (P. II. Sect. I. 1) as a dirty, cream-coloured pulp, or a paste of moistened white lead, which had been soiled, but at other times, when the blood was absorbed, the inner, and, in all cases, the outer surface of the cyst, exhibited the ordinary distinctive cerebriform character; and on scratching either aspect with a lancet, the granular matter was exposed situated between the two membranes. P. II., S. VII., 4, 6.

In those instances, again, in which the outer membrane had ceased to be transparent, the cysts, when insulated, displayed a cartilaginous looking exterior, having the yellow matter arranged on its internal surface covered by the inner membrane still diaphanous, although better organized than in those already described. P. I., S. IV., 1, 5; P. II., *passim*.

In proportion to the age of these cephaloid bodies, and perhaps also to the absorbing power of the female, they were found undergoing different degrees of diminution. In those possessed only of thin coats, or having the outler layer as the seat of thickening, the walls of the cysts speedily contracted and coalesced, when their centres exhibited, in the less organized, a delicate opaque streak; and in those better developed, a serrated, curved, and well-marked white line (P. I., S. II., 8, 10; S. IV., 1; P. II., S. I., 2, 6, 7,) or a stellated point, (P. I., S. IV., 1,) according as the cyst was of an elliptical or of a globular form.

This variety of cerebriform cyst, in which the walls were pellicular in their structure, or the outer coat only thickened, the granular matter being deposited in both cases between the layers, was met with in a recent state indifferently in immediate connexion with the existence of menstruation and of the first seven months of pregnancy, and in this latter case, and also, in a conversion of this form yet to be (20) described, they constituted the corpora lutea of Dr. Montgomery. P. I., S. II., 3, 6, 8, 10; S. III., 3; S. IV., 1, 5; P. II., S. I., 1, 2, 3, 5, 5a, 6, 7; S. II., 3; S. IV., 7; S. VII., 4.

B. In another variety of this granular deposition the new tissue was found external to the two innermost layers of the Graafian vesicle, these latter being, in such case uniformly, converted into a dense white body (16 B.) surrounded by an envelope of yellow matter (P. II. S. I. 4, 5, 6a, 8, 10, 11a, S. II. 2). Such eysts (corpora lutea of Dr. Lee) were never observed as an effect of menstruation simply, but were met with exclusively in the gravid female; although they were seen, as was sometimes also (P. II. S. I. 2, 7) the cephaloid body with soft coats (19 A.) just described, presenting double in some cases of single conception (P. II. S. I. 9, S. II. 4).

This form (19 B.) of corpora cephaloidea was generally distinguished by large, persistent, white, glistening cavities, and, when divided, by cerebriform striated rings, the matter of which latter was found nearly quite absorbed three days after parturition, (P. II. Sect. II. 2) and had disappeared entirely in another case (P. II. Sect. II. 4) three weeks after delivery at the natural term, the parchment-looking inner layer, with its delicate, transparent envelope, being left in the form simply of a dense white body. A modification of these characteristics occurred when the usual cellular connections uniting the elastic internal coat of the ruptured vesicle with the more external had given way, and permitted the former to become rolled up as an almost solid pellet within the granular matter still lined by the latter; (P. I. S. I. 4, 5, 8, 11b, S. II. 5) and another modification was when the granular matter, instead of suffering absorption, became more vascular, and converted into (20) a red body, (P. II. S. II. 5) precisely as in the former case (19 A.)

20. The fourth general state of the ruptured ovisac was peculiar to the impregnated and lactating female in the period between the eighth and thirteenth month after conception, and appeared to be a conversion of the forms (16 A. B. and 19 A. B.) already described, arising out of a higher and more perfect organization. The condition was not observed till subsequent to the seventh month of utero-gestation, or later than the sixteenth week after delivery, and in some instances as early as two, (P. II. Sect. II. 2) three, (Sect.

II. 4) five, (Sect. III. 1) ten, (Sect. IV. 1) and twelve weeks, (Sect. IV. 2) after parturition at the natural term, it was also absent.

Down to the seventh month of pregnancy, the cysts contained in the ovaries (P. II. Sect. I. 1, 2, 3, 4, 5, 6, and 7) did not differ in any respect from the cerebriform bodies found in the unimpregnated state, unless that they were sometimes plumper, more vascular, better developed, and had their inner layer more frequently thickened. At the ninth month, the yellow granular matter had lost the rhubarb-colour which it before this occasionally presented, (P. II. Sect. I. 5) had become more dense, and of a pale, slightly yellowish hue or fawn-colour, (P. II. S. I. 9) changing to a faint red (P. II. S. I. 8, 10) on the access of air. Its structure was now about an eighth of an inch in thickness, and appeared as if formed of extremely delicate fibrils, which lay obliquely across, alterations supposed to depend not only on vital causes, but also on the contraction of the cyst, the cavity of which, having its inner surface covered, (except in those instances (P. II. Sect. II. 5, V. 2, 4) in which the inner layer was the part thickened), by the pellicular internal membrane, was now reduced either to a curved groove or to a circular stellated point, according to the shape of the cyst; a configuration produced by the corrugation on the plastic cobweb structure of the inner membrane of the highly organized and elastic outer layer and cerebriform matter.

At the end of the first month after delivery (tenth month), the external ring was (P. II. Sect. II. *passim*) of a mottled yellowish-red, and sometimes of a decided rose colour, and became very florid on exposure to the air, its section having some likeness, in the oblique arrangement of its seeming fibres, to that of the left ventricle of the heart. In one case, at the end of the second month after parturition (eleventh month), this ring (P. II. Sect. III. *passim*) is described as being of a brownish red colour, and as resembling the horny and glistening tissue of the condensed cuticle around some kinds of clavi when newly pared; and in another instance, in which the second month was completed, it appeared as a corneous, grey-coloured, semi-transparent

substance, having a striking resemblance, in its linear arrangement and fleshy colour, to the human nail in the living subject, as it rests on the subjacent pulp; its colour when examined by transmitted light appearing to depend on the presence of red vessels, which in a case at the fourth month (thirteenth month), were seen proceeding (P. II. Sect. V. I.) from a capular investment.

In three instances of ovaries belonging to gravid women, which were observed, there were important modifications from those described in the structure of the red bodies. In one case (Sect. II. 5) while the redness was still situated in the outer layer of the Graafian vesicle, the inner layer, instead of being a mere pellicle, as was usually the fact, was thickened, and opaque, as in the cerebriform bodies (19 B.) already spoken of as having been seen only in the puerperal state; and in two others again (Sect. V. 2, 4), both the redness and thickening were situated in the inner layer, the cysts being obviously undergoing conversion into the condition of dense white bodies, (16 B.) just as often happens in the virgin. In one of the latter, also, (S. V. 2), the inner aspect of its vascular surface was covered with a yellow pigment of what seemed to be (corpora lutea 15 B.) disorganized blood.

21. The rose or red coloured (corpora rubra) fibrous bodies (20) now described, although, in their most usual form as consisting of an external very vascular portion, enclosing an opaque film, they were found exclusively in puerperal females, were yet not always present in the gravid or recently puerperal states.

Up to the seventh month of gestation cerebriform bodies only were seen, and in one case (P. II. Sect. III. 3) the same thing was observed eight weeks after delivery; while in another individual (P. II. Sect. II. 2) dying two weeks, and in a third (P. II. Sect. II. 4), three weeks, and in a fourth (P. II. Sect. III. 1), five weeks after parturition, neither rose-coloured nor cerebriform bodies were present, the only ovarian cysts detected being the two varieties of white bodies (16 A. B.), a state of matters which was renewedly observed at the eighth (P. II. Sect. III. 4), tenth (Sect. IV. 1), twelfth (Sect. IV. 2), and sixteenth weeks (V. 3),

and also at various (VI. 3, 4, 5, 6, 7, 8) more advanced periods after the birth of the child.

22. This excess of corpora alba over every other physiological appearance in the impregnated ovary, seemed to result sometimes, (P. II. S. V. 3) from a gradual obliteration of the vessels of the highly vascular outer coat and cerebriform matter lining it, which had constituted in succession a cerebriform body with transparent membranes (19 A.), and afterwards, a corpus rubrum (20) with single cobweb-like lining, and ultimately, a soft (16 A), white body; and, again, to be produced at other times (P. II. S. II. 2) by the absorption of the cerebriform matter which had been previously arranged external (19 B.) to the thickened inner and pellicular more external layer of the cyst; while in another description of cases (P. II. S. II. 4. III. 1, V. 2, 4) the total absence of granular deposit was noticed in such circumstances as to give much countenance to the supposition that in some instances of conception this phenomenon may not take place at all; but that, as sometimes occurs in the unimpregnated female, an increased vascularity and organization of the outer or of the inner layer of the ruptured vesicle is succeeded at once, without any such intermediate stage as involves (19 A. B.) the deposition of brain-like matter, by the formation respectively of a soft, or of a dense white body, as at 16 A. B.

23 In many puerperal women bodies of identical character, but in different stages of progression, were often found together, and it was then supposed that the best organized cysts were at once the most recent, and those which had furnished the fecundated ova; and that the others had been in existence for too long, although not necessarily a very long time, before the occurrence of conception, to permit them to take on any increase of development consequent on gravidity (P. II. S. I. 3, III. 4, IV. 12, V. 2, 4, 5, VI. 1, 4, 5, 6, 7, 8, 9, 10).

24. In other pregnant women, in none of which had there been twins born, and in one of which the fact of there being a single conception only, was capable of being demonstrated (P. II. S. 2), two bodies of a similar kind, and of equal organization, were found either in the same ovary, or in the two; and in such it was impossible to determine the pro-

ductive from the non-productive vesicle, and their rupture, therefore, was believed to have been coetaneous, and that while the ovum of the one only had been fecundated, the coats of both, alike capable of taking on a higher organization, had been exposed equally to the increased ovarian circulation consequent on utero-gestation (P. II. S. I. 6, 7, 8, S. II. 4).

[To be continued.]

ON CONSTITUTIONAL IRRITATION OR GENERAL DISTURBANCE.

BY T. WILKINSON KING, F.R.C.S.E.

[Concluded from page 270 of our last volume*.]

(For the Medical Gazette.)

Varieties, dependent on the blood.—Cachexiæ. Fevers. Repair. Inflammation; its differences, local and general.

WE may study with advantage the purely local causes of disease, and we may also do well to study those various peculiarities of parts which affect the course of disease; but, in the main, the essence of practical pathology is to consider not so much the morbid appearance, as the constitutional state to which it belongs—on which it depends. Purely local disorder arises from direct external influences *exclusively*; and so much of it as a perfectly healthy diathesis can affect is absolutely and only reparative, whether it be to detach a dead part, or close up a wound. Friction causes a corn. Some bodies throw up a corn (as a wart) too readily; others too tardily. One produces a bunion instead; that is, an evolution cellular instead of a cutaneous hypertrophy. Others, in peculiar states, from the very same external cause, run into ulceration, inflammation, or gangrene.

An external cause, in nowise different from the first, suffices to determine the location of exostosis, of struma, or of cancer; but no doubt the blood, from which every thing grows, must be altered before any of these last formations can be produced.

A certain pressure on a bone, like fracture, will cause a new deposit of bone; but the new growth ceases immediately that the cause is removed, unless constitutional circumstances of

a specific nature keep up a disordered train of actions. It is only in one sex, and at one season of the year, that the stag's horn, with its skin, hair, follicles, and nerves, can be built up from the blood. And how much depends on the perfection of the sex!

Tumid scrofulous scars, and indurated results of burns, are forms of hypertrophy. The first occur in succulent vascular individuals, and decline as their bodies waste; and the second are, in part, the effect of physical extension; yet even these depend greatly on the state of the constitution. A hollow cicatrix, soft full reproduction, and hard ligamentous bands, are not determined more by the nature of the injury than by the condition of the reparative supplies, and the local management of the case.

An examination of causes, in the method we are now engaged to pursue, may by some be deemed out of place, or far-fetched, or even presuming; yet we would not conceal our persuasion that some such a course is the only true one. And even though any one of the little processes we attempt to explain may still need a better historian, we yet offer our sketch with some confidence, feeling assured that astrology is not more different from astronomy, than common pathology from the narrative of morbid processes. A celebrated surgeon sets the account of *pathologers* against the successes of the knife; but we ask, is not that surgeon most like an astrologer who disregards the intricate course of nature from health to the restoration of health—the chain of events whose links we may (perhaps in total ignorance) strengthen or destroy?

Our endeavour will be to give or hint at views of processes, however feeble and partial they may appear, and to find glimpses of more general inferences.

We have seen that simple irritations are various; some physiological, some pathological, and some therapeutic. We resume the consideration of the origin of diseases, on the humoral principle, that a *vast number of morbid phenomena depend on excessive, deficient, or deteriorated nutrition*;* that is, that the blood is early affected in one of

* See also an account of Simple Irritations in a preceding number.

* Vide a Sketch of Humoral Therapeutics in the Provincial Medical Journal, Dec. 23, 1843, and in the Med.-Chir. Review, April 1844.

these respects, or perhaps only a part of its constituents is altered.

Let us see how we may rely on this doctrine. Let us consider it in relation to cachexia, fever, inflammation, &c.

Perhaps no subject forms a more natural commencement of this inquiry than the varieties of *cachexia*, which, however they may admit of elucidation by references to nervous functions, depend greatly on humoral principles, as we shall endeavour to shew. The *cachexia* may be studied in three classes: those in which marked visceral disease is the chief cause; those caused by continued excesses, or established sores or discharges; and those in which no marked traces of the above causes are discoverable. Cases of complicated origin will often be met with. Those which seem rather to depend on specific circumstances, as syphilis and cancer, might form a fourth class. They may be more readily examined independently.

The *cachexia* which depend on fixed disorganizations of the heart, lungs, liver, bowels, kidney, or nervous system, &c. are too strongly marked in the general to require illustration. It is very important to remark, that whether as physical, humoral, or nervous difficulties, the knowledge of them, especially humorally, tends to explain the nature of other cachectic states. It is not, however, to be forgotten, that disorganizations of the excretory glands and surfaces owe their origin, in the main, to disordered blood; and so all pernicious inflammations. The rupture of a valve may be simply mechanical; but the softening which mostly precedes the rupture is deteriorated nutrition or inflammation.

No one will, of course, dispute the disordered states of the body, and of the fluids in particular, that arise from indulgences in eating, or in drinking (with neglect of food), bad hours, habits of excitement; from exposure and loose pleasure, and habitual losses of blood, mucus, or of pus. Here is a well known series of *cachexia*; and it is not to be doubted that these, in a good measure, are in their essential nature humoral. The use of opium and tobacco, and the abuses of medicines, and poisonous as well as deleterious occupations, however complex their influence, owe their chief effects

to deteriorations of the blood. We conceive that the old idea of latent disorder (concocting or brewing) deserves the most ample and attentive consideration, as, in fact, the chief part of all constitutional irritation. The effects of starving or of over-feeding, and of many kinds of diet, are too well established even as humoral cases to demand explanation, as in gout, scurvy, &c. Methods of treatment, as by regimens, bleeding, issues, or medicines, must be indebted greatly to the changes they produce on the blood for the ultimate benefit imparted to the whole body.

Cachexia appears also to develop itself simply in connection with a disordered balance of the humoral functions, as with impaired digestion, inactivity, or defective excretions. Heat seems to drive the system to wasting. Cold may retard the whole to the same effect. Slight or repeated exposures, when vigour is wanting, cause *marasmus*, with scarcely discernible febrile or inflammatory disturbance; and the susceptible frame may only be rendered more subject to these derangements by the enervating influence of summer. From a review of all these known causes of *cachexia*—the effects of climate, season, habits, accidents—we may be enabled to form some estimate of another set of causes (themselves consequences), which are doubtless still among the more mysterious parts of pathology. We refer to the initiative state of *fevers*, and to the spontaneous *phlegmasia*.

Perhaps it is scarcely too much to say, there is no such thing as simply catching a fever*; for previous *cachexia* must be inferred, at least commonly.

It is a very forcible truth, that when an individual has some local disorder, as a catarrh, or a sore, which, like an original organ, varies its activity in proportion to the disturbances to which the whole combination of external influences may subject him, he is almost exempt from fever or other inflammation. On the other hand, his chronic variable issue, his supplementary depurating humoral function, be suspended, and he becomes even more certainly than another the victim of acute

* This strong assertion may be excused, if only to illustrate our meaning. Such cases as small-pox are not included.

disease. A strong man, after injury, has a tedious necrosis, discharging good pus; when it heals up, he has sanguineous apoplexy. In another, a wide old ulcer produces every week or two, with febrile relapse, a coating of fibrin: if the wound but partially heal, he has a solid pneumonia. It is too easy to forget the needful consideration of the diathesis. It is said watery purgatives cure a dropsy; but is it not much more true, that the drastic aperient acts peculiarly on such constitutions? How would it act on one prone to diphtheritic enteritis?

When typhus, yellow fever, or plague, cholera, influenza, or erysipelas, occurs sporadically, little or nothing is said of contagion; but not so when the endemic fever is epidemic. When the revolution of the seasons, and the set train of events which they entail in particular spots, bring about a common cachexia, a general humoral diathesis, especially amongst those most exposed, many suffer in the same way; and we are inclined to look for new and fearful causes of the evil. It is only towards the end of summer that fruit and vegetables disturb the bowels in London, and only in particular seasons that puerperal fever is carried about by the accoucheur. Erysipelas is contagious exactly in proportion to the number of cases in the hospital at the same season. Where plague is habitual, contagion is little considered, excepting only, perhaps, when the disease is most rife.

Inflammation.—If we regard hypertrophy and mere reparative inflammation as simply increased capillary function, we may consider inflammation as increased and deteriorated capillary action; but this action we refer to the blood humorally as nutrient. Atrophy, ulceration, and often death, seem to be only different humoral effects.

It might almost be said, that actual destruction is the only limit to the healthy powers of repair. History records the most fearful operations, injuries, and exposures, to have been endured without loss; yet a bruise, a graze, or a puncture, with constitutional disorder, is almost more rapidly fatal than irritative fever alone.

We think it a material fault to describe as inflammatory any truly healthy act of repair. This act is es-

entially distinct from every morbid process; but when it is found that deteriorated actions attend, the term inflammation, or an equivalent, is required to distinguish the morbid phenomena.

We have known a cart-wheel pass over a lad's knee, and lay open a pouch posteriorly large enough to lodge the fist, and all become closed by adhesion; and, indeed, there is no end to the facts of this kind which might be collected. A negro received fifty-three sabre cuts: both glenoid cavities were laid open. In a month he was walking about. A young gunner has his arm shot away, or a man swimming is torn by a shark, and the bowels hang out; amputation is performed at the joint, and his convalescence is almost uninterrupted. These are not isolated facts, and the triumphs of desperate surgery are still less so. We do not mean that the converse of all this is uninstructional.

Sometimes only compound fracture has irritative fever, but usually the granulating cavity has not, (it is a proof of the opposite diathesis) unless fresh disturbing causes be applied; and thus, as often happens, a renewal of fever is produced. Even after the local mischief is totally repaired, fever returns, not less *irritative*; and phlegmasia, suppuration, or hydrops, fatal or not, demand all our watchfulness. These are neither the cause of the fever, nor of its cure. They are casualties, more or less healthful or mischievous throughout; and their course has no precise relation to that of the fever. It is most true, that *with* reparative action we very commonly see traces of inflammation, that is, of morbid action; and it may be necessary to glance at the series of purely healthy processes, in order to enforce the distinction we are advocating. It cannot be too well remembered, that there is a long list of cases in which nothing seems done needlessly, or out of the way,—where the most limited local disturbance is all that is discoverable; and even the presence of foreign bodies, and the operation of various untoward circumstances, external and others, are not found to interfere with the steady and speedy restoration. "The flesh heals well" so long as the humoral condition of the frame is not deteriorated. How great an injury is perfectly repaired in the healthy body!

how alight a one determines irrepressible inflammation in the disordered constitution! Yet we would not doubt that one cut off by inflammation set up around a corn, might, under other circumstances—say, a favourable sojourn on the coast—have revolutionized his system and his blood, and have become capable of repairing considerable mechanical injuries. To us the rhinoplastic operations, and the reunion of detached fingers, do not seem so much to indicate “strength of vitality,” or “degree of vital force,” as simplicity and purity of action and blood; the absence of deterioration in fluid and solid—nutrient or reparative action being undisturbed.

In proportion as cachexias or visceral disorganizations are advanced, or nutrition is perverted, inflammation is of a worse kind. The diathesis which produces croupy false membranes in any mucous passage, may be transitory, or repeatedly recurrent, or at once fatal, and that even at any age of life. In a violent attack of erysipelas, the consequences depend greatly on the comparatively healthy state of the body, the importance of the parts invaded, the absence of fresh aggravating causes, and of injudicious remedial measures; but do not all these considerations refer in part to the blood, as liable to defect, and capable of repair?

We do not hesitate to assert, that there is no healthy spontaneous inflammation. Slight pleuritis, terminating in very partial adhesion, might be advanced as an objection to our statement; but what is the truth of the case? A comparatively healthy body has been subjected to a severe disturbing cause; the progress of events and remedies renders the effects transitory, and the mischief is repaired in the most healthful manner the case admits.

A lecturer on inflammation (MED. GAZ. 1840, page 306) speaks of active phlegmon and inflammatory fever in a *healthy* man; but although he still wishes to maintain the old views of reparative healthy and morbid inflammation, we suppose he would admit that phlegmon after simple injury must imply deteriorated health—we would say, morbid blood. There is no limit to the insignificance of the local cause of phlegmon and of irritative fever. A spark is too much in a powder magazine. The most accustomed ex-

ercise, the most ordinary exposure, may prove the initiative of fatal disease. How should a shoe else grow old and easy over a corn, and yet induce at last rigor, inflammation, and death?

The author referred to continues thus:—“Does ulceration occur in the stomach or intestines, and threaten to penetrate through them? Inflammation will often anticipate and provide against the danger, glue the threatened membrane to whatever surface may be next it, and so prevent that worse and universal inflammation of the peritoneum, and the almost certain death, which the escape of the contents of the alimentary canal into that serous bag would infallibly occasion.” (MED. GAZ. 1840, page 305.)

These, we believe, are the established opinions of inflammation, but we wish to offer a plain objection to them. If the parietal peritoneum inflames, in consequence of apposed disease, it is the effect of direct local deterioration of its own tissue; and whether the serous inflammation be limited or diffused, the state of the individual's body alone determines. Sir A. Cooper recommends, when the dura mater has been penetrated, and the arachnoid cavity exposed, as in trephining, that the close layer of serous membrane should be wounded with a lancet, in order to insure adhesion, and so prevent diffused inflammation. We deem it altogether an error to refer the spreading of the mischief, or its arrest, to any such trivial local circumstances.

That modification of nutrition which is called reparative action should be ever regarded as of a very simple kind, whatever variety of tissues may be concerned. It excites comparatively no general disturbance, and is attended with no kind of mischievous or unnecessary local change or product. Parts greatly injured may die, and absorption must separate the useless living from the dead matter, and the exposed surface must granulate; but in the healthy body all this is conducted with the least possible disturbance locally or generally; and great and deep lacerations may heal up, as it were, by adhesion, without gangrene, though not without absorption, and without supuration, or with only slight superficial granulation. We do not assert that slight injury is equally reparable in all parts as joint, skin, and nerve; nor

do we forget that the mode of repair of different parts involves specific difficulties, delays, and dangers. We admit that some of these may even be justly considered *nervous*.

When the course of acute or chronic disease is arrested by salutary constitutional changes, an empyema dries up, a psoas abscess shrinks, scrofulous matter becomes permanently shut up and fossilized, the varying action and effusion in hydrocephalus is arrested, the oldest catarrh disappears; and what is the history of the whole? it is merely the least modification of healthy process the case admits of. But if inflammation and any one of its pernicious products interferes with the series of changes, there is no remedy until again the general balance of the functions and the repairing diathesis are restored. The constitution peculiar to repair is a great point for medical study. It is a specific state, rarely pure, liable to many perversions, variable in a great degree, but a power to which, if it should but act, the physician may be well content to be subordinate. It is well if the physician possess but a crude notion of the means of liberating, promoting, or facilitating, the general state which is essential and peculiar to repair. With this state, foreign bodies are almost harmless. The brain may be sliced, joints laid open, the chest pierced through, the abdomen explored, limbs crushed, and the bare essentials of life being retained in integrity with healthy blood, the least complicated course of repair that the circumstances allow of is steadily carried on. Not so if dust in the eye, a hang-nail, or an old obstructed follicle, be attended with what old Wiseman called "a gross habit of body."

It is usual to say of the various morbid inflammations, whether spontaneous or traumatic, that they may end in resolution, which event, if analysed, amounts only to this,—that at a certain state and period repair begins. With better blood, we have contracting capillaries, only due nutrition, and no more of deposit, absorption, or secretions, than existing local particulars strictly determine. Injured bone causes just enough of new ossification*. A divided muscle is repaired

by ligament, or rather cellular membrane, which active extensions convert into ligament. Cicatrization arrests the causes which induced granulation and exudation. Even the irrecoverable changes of inflammation, as tumefaction, softening, or induration, will thus be reduced or confined to the smallest limits.

After simple reparative acts, all the grades and varieties of inflammation, between the least unhealthy, and those which are the most so, require to be considered separately, and in order. But we may not expect to find the course of each uniform; the very principle of medical interference is, that the worse actions are susceptible of being converted into the better, as the better may relapse into the worse. Need we repeat that action with us means process?

[To be continued.]

CASES OF POISONING BY CENANTHE CROCATA.

By P. BOSSEY, Esq.
(For the Medical Gazette.)

TWENTY-ONE convicts were employed, on the 4th Feb. 1843, at the mortar-mill situated on the banks of a canal in the Royal Arsenal at Woolwich. At 11 o'clock in the forenoon eight or ten of them went round the building to an adjacent pond of water, in order to wash their spades and boots. One man (Chamberlaine) strayed away from the rest, and found this plant growing near the brink of the canal, the leaves and roots of which he mistook for celery. He dug up some, washed, tasted, and conveyed it to his companions. Several of the men returned to the spot, assisted him to obtain more of the roots, ate them freely, and distributed portions among their fellow-workmen who remained within the building.

At 20 minutes past 11, under the direction of the keeper, they were all about to fall into ranks for the purpose of returning on board-ship to dinner (most of them still eating and putting roots into their pockets), when one (Wilkinson), without any apparent warning, fell down in strong convulsions. The struggling was soon over; he became better, but retained a wild

* Where the new bone hardens, the mass diminishes, parts not serving for support being removed.

expression in the countenance, which was pale, and in a short time he had another fit. Whilst they laid him upon a shutter, a second individual fell (Knight), and before they reached the yard adjoining the hulk, a third (Wilson) and a fourth (Salt) had also fallen, and were convulsed.

I arrived to give assistance about a quarter before 12 o'clock. Nine stout young men were at this time convulsed and insensible. The three worst, Wilkinson, Knight, and Wilson, were lying in a shed; Chamberlaine, Gundle, and Jeffs, had just fallen in the yard; and Williams, Jones, and Salt, were struggling on the deck of the vessel.

It was manifest that Wilkinson was dying. His bloated livid face, the sanguineous foam about the mouth and nostrils, the stertorous snort and convulsive breathing, and the extreme prostration and insensibility, plainly indicated that every remedial measure would be useless. Nothing was done but to raise the head and shoulders, and he died in five minutes.

Knight had been strongly and repeatedly convulsed, and appeared to be fast hastening into the same apoplectic condition. He was insensible, speechless, the pupils dilated, the face swollen and livid, the breathing laboured, and the limbs convulsed. To make him swallow was impossible; the rigid jaws were therefore forced asunder, and, by means of the stomach-pump, warm water was abundantly introduced and withdrawn from the stomach. Some leaves were extracted with the fluids, but the instrument was worked with the greatest difficulty owing to the severity of the convulsions. He died in a quarter of an hour.

Wilson had assisted to carry the two former: when near the yard he was observed to look pale, and soon fell convulsed. He struggled so violently that several strong men could scarcely hold him. After the fit he was restless; consciousness partly returned; he answered "yes" when his name was loudly called, and swallowed an emetic solution of sulphate of copper. No vomiting was induced, the convulsions were renewed; the stomach-pump was passed, but extracted only fluids. A collapse threatening immediate dissolution followed; his strength was gone, face pale, pupils dilated, breathing convulsive, and he appeared dying. After

some time the stomach-pump was again employed, and small portions of the root, with a few leaves, withdrawn. Convulsions returned, with strong struggling, and about half-past 12 o'clock, in a fit, he suddenly died.

Emetics of salt and mustard, with warm water, were administered to those who had fallen in the yard, under which they vomited freely, and discharged a large quantity of imperfectly masticated root, and were thereby greatly relieved. The convulsions ceased, sensation and reason were restored, but there remained giddiness, pallor of the face, dilated pupils, coldness of the extremities, much weakness, severe rigors, and a slow feeble pulse. Further vomiting was promoted, and more of the root discharged. Friction and warmth were applied to the extremities, whilst ammonia and rum with thin gruel and other drinks were administered internally till reaction was more fully established.

Emetic doses of the sulphates of zinc and copper, and also mustard and water, were given without effect to the patients lying on the deck of the vessel. They were also bled very largely both from the arms and jugular veins. The introduction into, and removal of warm water from, the stomach by the pump brought away small portions of the noxious roots. Cold affusion upon the head perseveringly used lessened the struggling and produced some exhaustion. In three cases (Salt, Williams, and Burgess) the subsequent fits became less violent; they passed into a state of maniacal delirium, with much jactitation of the limbs, and after some hours were removed into the hospital. But in one more patient (Jones) all these remedies were ineffectual: he died convulsed at a quarter before 1 o'clock. As a last effort, the trachea was carefully opened by an incision, and artificial respiration kept up, but life was quite extinct.

Several of the men who had eaten the root, seeing the others suffer, took the salt-water emetic with success, and had no symptoms of being poisoned; others felt giddiness and faintness in a slight degree, and at 6 P.M. there were upon examination eleven who required watching, and were therefore sent into hospital.

Extracts from Notes of Cases in Hospital.

Feb. 4th.—Jeremiah Chamberlaine, æt.

24, admitted at 6 P.M. in slight stupor; countenance anxious, depressed; is drowsy; the eyelids half closed; pupils dilated; tongue clean; skin cool; slow pulse. Took a purging draught, and an enema of salts and senna, which produced two motions, the first principally the injection; the second, copious, fluid, brown, and mixed with white root, resembling what they had eaten.

Purgatives repeated, with magnesia.

10 P.M.—No motion; countenance improved; sleeping.

5th, 1 A.M.—Is sick, and looks worse; countenance anxious and sunken; pupils dilated; the hands and face feel warmer; complains of pain in his chest and abdomen, the latter is hard and tender; no further motion; tongue clean; pulse feeble; seems weaker.

Ordered Ammonia, &c.

3 A.M.—Is warmer; pulse stronger; sleeping. Bowels once opened.

10 A.M.—Countenance improved; mouth dry and parched; thirst; tongue slightly coated; tenderness, hardness, and pain in the abdomen; no further motion; no urine since midnight.

Purgatives continued.

4 P.M.—A sudden distension of the abdomen, with shortness of breathing; pulse 66; lies in a perfectly relaxed position; pupils dilated; no pain or headache, and no motion.

Purgatives and Enemata repeated, with Asafoetida.

Midnight.—Has passed one motion, copious, fluid, dark brown in colour, with pieces of the root discernible. No abdominal pain; urine thick, and dark-coloured.

6th, 8 A.M.—Is much better. Abdominal swelling and tenderness gone.

4 P.M.—Tongue white; pupils natural; urine plentiful, dark in colour, with a thick yellowish sediment; had three motions similar in character.

7th.—Tongue white, red at the edges, but recovering.

8th.—Pain in the head; bowels confined; tongue cleaner; urine free, dark-coloured, with sediment. Took castor-oil, which produced one copious fluid motion, yellow in colour, and in which the root can still be seen.

17th.—Discharged recovered.

John Williams, aged 22, admitted 6 P.M. on 4th February, in the same comatose condition: sleepy; roused with difficulty; has had one motion, natural.

10 P.M.—Feels a pain in the breast. Has just vomited a dark-brown slimy fluid. Feels better, and his countenance improves.

Midnight, 2 and 5 o'clock.—Sleeping.

7th.—10 A.M.—Feels quite well. Has passed motions in which a small quantity of the root is seen.

8th.—Appeared quite recovered, and was discharged to duty.

9th.—Readmitted in consequence of an attack of syncope. Tongue slightly coated; no pain.

Ordered a calomel purge.

10th.—Had three motions, in the first of which the root was still seen, but the particles were much smaller.

Repeat the purgative.

17th.—Discharged recovered.

William Jeffs, aged 23, when admitted at 6 P.M. on the 4th February, had slight symptoms of coma and exhaustion, which went off after free purging, and as he seemed quite well was discharged on the 8th.

10th.—Readmitted faint and collapsed. hands and face cold; lips blue; headache and giddiness; tongue moist, slightly furred; injection of the eyes.

A Calomel purge.

At 4 P.M. had a copious yellow motion, in which the root is plainly seen.

11 and 12.—Slight fever, with pain at the pit of the stomach.

V.S. ad 3xij. Purgatives and salines.

13th.—Still feverish. The pain in stomach gone; slight pain in the left side; urine plentiful, dark-coloured, turbid; bowels confined; abdomen rather hard.

Went on well till the 22d February, when the tenderness at the stomach was renewed, with giddiness, thirst, and pain in the right side under the ribs.

Twelve leeches were applied, and purgatives with salines continued.

23d.—Less abdominal tenderness; slight giddiness; fever subsiding.

March 3d.—Discharged recovered.

Joseph Salt, æt. 17, admitted Feb. 4th: though he continued in a state of delirium and insensibility, yet his exhaustion rendered it needful to convey him even with care in a cot to the hospital. At 7 P.M. he was restless, and with difficulty kept in bed; his lips livid; breathing hurried; pulse soft; skin warm; pupils dilated. When roused he did not speak, but stared vacantly, and seemed in a state of madness. The bowels moved involuntarily.

At midnight.—Not so restless; lies in a stupor, but when roused stares wildly.

5th.—At 10 A.M. more sensible; is very cautious before he drinks; bowels moved twice.

Noon.—Somewhat rallied, but still wild,

restless, and insane; the tongue cannot be seen; pupils natural.

4 P.M.—Quieter and sleepy. Being roused, he moans, and complains of pain in the left side; the breathing is laboured, but less hurried; the face flushed; the tongue, protruded with difficulty, is swollen, white, and blistered; a short cough; much mucus in the throat, raised with freedom; the tip of the nose very red; eyes natural; pulse soft, feeble, 78, much accelerated by slight exertion. The cutaneous sensibility greatly exalted: when touched he manifests great uneasiness; the slightest pressure on any part of the abdomen causes great pain; no hardness or distension; urine clear; penis retracted; the surface of the body cool. Being left alone he is soon asleep; moans and breathes heavily. Purgatives and enemata have been given with difficulty. He is now ordered magnesia, ammonia, and effervescing draughts.

6th, 8 A.M.—Looks worse; breathing short; face flushed; mouth parched; thirst. Great pain in the left side, it is very tender when touched; cannot bear to be moved, nor to drink any thing hot; tongue white, its edges ulcerated; much rattling of mucus in the trachea; pupils natural; pulse feeble; belly very tender.

Ordered twelve leeches to belly; blister to chest; purgatives—Castor-oil, Calomel, &c.

Evening.—Breathing laborious, hurried, with loud tracheal rattles; the tongue moist, white, its edges sore; pupils natural; face, nose, ears, and lips, excessively hot and flushed; skin hot; abdomen excessively tender; pulse soft, greatly accelerated. Lies in a state of stupor; sleeping much; expectorates a white frothy phlegm; desires cold drinks.

At midnight, and at 3 P.M. this day, passed motions dark-brown in colour, containing much mucus, and small pieces of the root.

7th, 8 A.M.—Slept at intervals, and seems better; less flushing in the face; breathing easier; tongue white; pulse fuller, about 100; tenderness of the abdomen. Had two motions: one, very bilious, contained smaller particles of the root.

Continue the Calomel Pill. Milk diet; demulcent drinks continued.

6 P.M.—Passed two motions this day; each contained many particles of the root. Breathing easier; less fever; belly tender; pulse soft, 120.

8th, 8 A.M.—Slept well; tongue moist, coated, red at the tip; belly extremely tender; hot skin; breathing easier; makes water with pain; the urine clear, high-coloured; no motion since yesterday; expectorates a heavy greenish-yellow matter; cough less frequent.

Castor-oil, with mucilage, repeated, and the antimonial mixture every two hours.

1 P.M.—No motion; belly very tender; increased flushing of the face and heat of skin; tongue white, rather swollen; pulse soft, 112; is hoarse. Pressure on the throat gives pain; it is sore when he swallows; frequent cough, with copious purulent expectoration.

V.S. ad 3vij. Pergat medicamentis.

6 P.M.—Less fever; breathing easier; had one motion, light brown in colour; cough and expectoration frequent; mic-turition painful.

Low diet; blister to back of neck.

9th, 8 A.M.—Had one motion during the night; headache; great tenderness in belly and side; tongue coated white, its edges red; still hoarse; breathing easier; has fever.

Saline mixture every four hours.

9 P.M.—Had no motion to-day; abdomen tender; breathing much shorter; face flushed; skin hot; tongue white, red at the tip. Ordered—

Calomel, with Castor-oil mucilage, and Tr. Op. Hot fomentation to the belly.

10th, 10 A.M.—Sleeps much; face livid; pulse feeble, 120; breathing quick; still very hoarse; spits a large quantity of heavy purulent mucus; bowels not open; mic-turition easy.

Repeat the Calomel, with Castor-oil and saline mixture.

Noon.—The breathing more oppressed, and the countenance greatly congested.

Was bled to 12 ozs., and ordered Antimonial Mixture every two hours, and an Enema.

10 P.M.—Passed three motions containing much mucus; belly tender; is very hoarse; spits the same yellow matter, &c.

11th, 10 A.M.—Face congested; sleepy; breathing laborious; pulse soft, feeble, very frequent. Seven motions during the night.

Ordered a cordial draught; wine and sago, &c.

12th, 10 A.M.—Looks worse; face livid; eyes half closed; is sleepy, breathing short; is very weak; has diarrhoea; the belly very tender and painful.

Ordered wine and sago, and Carbonate of Ammonia; 1 gr. Calomel every two hours.

10 P.M.—Sleeps much; eyes very much sunk; breathing very short; cough; expectorates with great difficulty the same dark-greenish matter; is delirious; face more flushed.

13th, 10 A.M.—Still delirious; sleeps

much; slight mucous rattle in the trachea; cannot expectorate; is fast sinking.

Noon.—Much worse; rattling increased. Died at 3 P.M.

This young man was bled largely the first day, but during his subsequent illness the extremely irritable condition of the nervous system, and the severe bronchitis, prohibited active depletion.

The post-mortem inspection shewed that many important organs were very seriously injured.

The trachea and bronchi were injected, and the smaller bronchi filled with mucus. The left pleura was lined with lymph, and its cavity filled with serous effusion. The stomach and intestines were pink on their external surface, the intestines glued together by adhesive matter; and there was much peritoneal effusion, with flakes of adhesive lymph. The mucous membrane of the stomach and bowels was softened, thickened, and everywhere coated with an abundance of mucus. On washing this off, the membrane was much injected. The vessels of the brain were more injected than usual, and there was slight serous effusion beneath the arachnoid.

Abel Burgess: first fell convulsed on the deck of the vessel: was bled very largely, had emetics, the cold affusion, the stomach-pump, and subsequently stimulants.

Feb. 4th, 6 P.M.—Still slightly collapsed; loud rattles in the trachea; countenance anxious, depressed; complained of pain in his breast; breathing short; tongue swollen.

Ordered a strong cathartic, and an enema of salts and senna, with occasional doses of ammonia.

10 P.M.—Countenance improved; is warmer; the pain is more severe in the right side; the rattles in the throat louder.

Ordered a mustard-poultice, and as before.

Midnight.—The pulse stronger; pain in the head; more restless; breathing short. On admission he passed a natural motion. None since.

5th, 10 A.M.—Feels better; pain in the head; slight pain in right side; tongue clean, swollen; the rattles still heard. At 4 A.M. he had two motions, both of which contained much of the root.

Noon.—Is hot and feverish; the respiration hurried; pulse frequent and feeble; still complains of pain in the side; pain in chest gone; tongue red at the tip.

4 P.M.—Face swollen, flushed; eyes injected; pupils natural; tongue moist, clean; much mucus in the throat; coughs slightly,

and expectorates with difficulty a reddish mucus; the cough gives pain in the region of the liver and in the head; pulse full, 120; thirst; abdomen soft, without tenderness; semiprurism. Passed a pint of urine, reddish, and depositing a copious white sediment; feet warm; the bowels not moved since morning.

Repeated the Enema.

6th, 8 A.M.—Bowels have acted, and he feels better, but still has pain in the head and right side; respiration hurried; slight rattling in the trachea; urine reddish.

8 P.M.—Respiration less hurried, but coughs more; rattling in the throat declining; expectorates a thick reddish mucus; pain in the side; urine thick, high coloured; had two fluid motions.

Ordered castor oil, and to take calomel every three hours.

7th, 8 A.M.—Passed a good night; four motions, partly bilious; abdomen free from tenderness; expectoration bloody; pulse frequent, soft; tongue white; skin warm; the rattles gone.

Continue calomel, &c.

6 P.M.—Breathing short and hurried; pulse 120; cough increased.

Bled to 10 oz. and continued the calomel.

8th, 8 A.M.—Has passed more of the root; breathing easier; cough and expectoration as before; tongue clean; urine dark in colour, with sediment; slight rattling heard this morning.

Antimonial mixture, &c.

1 P.M.—Has passed another motion containing some root; pulse 108, soft; on the right side of the chest there is dulness on percussion, the natural murmur wanting, a short bronchial sound; on the left side, sonorous rattles, the heart's action quick, weak, with a thrilling sensation communicated to the hand; tongue white; face flushed.

The bleeding repeated. Pergat cæteris.

6 P.M.—Breathing with more ease, but the right side still painful.

9th, 8 A.M.—Breathing easier; cough less; tongue clean; countenance improved; sputum less bloody; face not flushed; thirst gone; is very weak; there is great tenderness on the right side; has had one motion, thin, yellow in colour, mixed with black or dark brown specks, the remains of the root.

Ordered saline mixture every four hours.

10th.—Tongue moist; skin cooler; pulse soft, 90; breathing short; cough troublesome; sputum dark, but not so bloody; still a little pain in the right side; bowels not open.

Ordered castor oil, and a blister to chest.

10 P.M.—Cough distressing; breathing short; tongue coated, moist; expectorates a less bloody mucus; moans considerably.

Ordered antimonial mixture every two hours.

11th.—Breathing short and difficult, especially when he is moved; cough troublesome; tongue clean, moist; skin not so hot; sputum less bloody; had nine motions during the night.

Suspend the antimony; give him a cordial draught and salines.

12th, 10 A.M.—Breathing easier; cough troublesome; expectoration copious; a pain in the right side; tongue clean, moist; abdomen tender; had four motions.

Ordered 1 grain of calomel every three hours.

13th, 10 A.M.—Breathing more oppressed and difficult; countenance anxious; is restless, endeavouring to get up; face a little flushed; tongue clean and moist; is drowsy; the pain in the right side has increased; expectoration very copious, loose, and less bloody; urine plentiful, and still thick; had two bilious motions in the night; feels himself worse.

Ordered to continue the calomel, and a blister.

8 P.M.—The cough and breathing easier; countenance improved; expectoration easy, and becoming white; has passed three bilious motions.—Pergat.

14th, 10 A.M.—Is worse; breathing more difficult; pulse feeble; features anxious; expectoration easy and copious; rattling in the trachea; tongue clean, moist; had one motion, dark and bilious.

Ordered wine and sago, and to continue the calomel.

6 P.M.—Approaching delirium; restless; pulse very small and feeble; breathing short; countenance anxious; had three motions during the day, dark and greenish.

Ordered ammonia and stimulants.

10 P.M.—Appears to be fast sinking; the countenance pallid; eyes half closed; cannot lie down; loud mucous rattles in the trachea; expectorates with great difficulty.

Ammonia and wine freely.

Midnight.—Still sensible; much weaker; rattles louder; breathing shorter.

15th.—Sat up in bed till half-past 2 A.M., when he laid back on his pillow, and instantly died quite easy.

On examination of the body there was found a considerable development of the papillæ at the root of the tongue, and of the mucous follicles throughout the œsophagus, stomach, and intestines. The surface of the

mucous membrane was lined with a tenacious secretion, which, being washed away, presented the membrane itself, thickened, softened, and more than usually vascular.

The lining membrane of the trachea and bronchi was deeply injected, the smaller tubes being choked with a frothy bloody mucus. The lower portion of the right lung in the state of red hepatization. Both lungs were heavy, contained much blood, and interspersed throughout their substance, but especially in the right, were various spots of ecchymosis from extravasated blood—probably effused during the primary convulsions.

The right pleura was adherent, and lined with the products of recent inflammation; and in the back of its cavity there was considerable serous effusion lying upon a surface covered with fibrinous lymph of a pale straw colour.

The pericardium was largely distended with a greenish coloured serum.

The vessels of the pia mater were fuller than usual. The brain was not unhealthy; it presented rather more bloody points, and there was also slight serous effusion.

In this, and the former patient, the tremendous shock which the powers of life had sustained by the first direct operation of the poison, and probably its continued influence in proportion as it was digested in the body, appeared to render the state of reaction one of peculiar irritability and danger. There was a tendency to swooning and collapse; a variableness in the condition of the pulse, the respiration, countenance, and temperature, that seemed to prohibit further depletion till two or three days had elapsed; and the local inflammations which successively arose in different organs were not afterwards controlled by the liberal use of the ordinary remedies.

The remaining patients did not suffer any urgent symptoms: under the free use of purgatives they passed considerable quantities of the root, and were in a few days discharged.

Examination of Wilkinson (No. 1), 47 hours after death.

The appearance of the body very stout and muscular; extremely rigid; the fingers stubbornly contracted; the thumbs turned in upon the palm; the nails blueish. General lividity, not very intense, but in patches anteriorly, while the whole dorsal surface presented a deep purple hue, except in the hams, where the hue was redder, and on the parts subjected to pressure, as the scapulæ and nates, over which it was absent. The scrotum and penis slightly livid; the former not distended.

The countenance livid, somewhat swollen, especially beneath the jaw; the eyelids somewhat open; conjunctivæ slightly congested above and laterally; slight opacity of the cornea; the pupils dilated, the irides being about a line in breadth; the lips, gums, and ears purple; a frothy secretion filled the nostrils; the tongue bitten at the tip, with an appearance of blood between the teeth.

The chest flattened, contracted above, duller than usual on percussion; there was unusual distension and resonance of the abdomen, especially in the epigastric region.

On dividing the scalp, fluid blood escaped more freely than usual; the pericranium natural; the skull very thick; on the interior of the skull were a few injected veins; the dura-matral surface was thought to be not much injected; the longitudinal sinus contained only fluid blood, not the slightest trace of a coagulum. The veins of the pia mater had a natural appearance; they certainly were not distended, as they did not reach a level with the top of the convolutions. Not more than the usual quantity of blood in the sinuses, but it was of a very black colour and perfectly fluid. There was a slight degree of serous effusion, a clear gelatinous deposit under the arachnoid, and some globules of air were seen in the veins. The processes of pia mater dipping between the convolutions were darker than usual; the plexus choroides also darker, being of a plum or damson colour. The cortical structure of the cerebrum was not redder than is usual in recent brains; more bloody points were seen in the centrum ovale; no serum in the ventricles; some veins were ramifying on the corpora striata; the substance of the corpora and thalami were thought to be slightly redder than usual. The veins and sinuses beneath the posterior lobes of the cerebrum were fuller; the veins on the pons varolii, the medulla oblongata, and about the roots of the nerves, turgid. The substance of the cerebellum, pons, and medulla, was somewhat redder than usual. On dividing the veins and arteries of the spinal marrow, a quantity of fluid blood flowed into the base of the skull. No water at the base.

The veins beneath the integuments of the back were congested. On opening the vertebral canal the theca spinalis had a reddened appearance; the vertebral vessels were injected; the veins and sinuses filled with black fluid blood; the substance of the spinal marrow, especially its internal structure, redder than usual; at the lowest portion, in the lumbar region, there was a little serum.

The tongue was large, and covered with a white fur; the papillæ at the base remarkably elevated and vascular; the soft palate, tonsils, and pharynx, covered with a glairy mucus,

and presenting a general blush of dull and somewhat livid vascularity, deepest in those parts where the fluid gravitated, as in the little cavities between the epiglottis and the tongue. The epiglottis dull, with vascular lividity, turgid veins being seen upon it. The pharynx and œsophagus had a white appearance, contained some mucus, and portions of the root.

The trachea and bronchi were lessened in diameter, appearing contracted, and the lining membrane intensely injected with dark blood. This injection was partly concealed by a thick smearing of reddish mucus, which also filled up the smaller bronchial tubes. The lungs were purple and heavy, being gorged with fluid blood; and there were several recent small extravasations of blood scattered through their substance.

The stomach and intestines externally were pink in colour and distended with air; the stomach also contained a little fluid, some of the root, and was, with the intestines, every where lined with a thick viscid mucus. The mucous membrane was thrown into folds, forming prominent ridges, intersecting each other like meshes. After washing away the mucus, when the membrane was placed under water its surface had a mammillated appearance, the follicles being particularly distinct, erect, and abundant. Held up before the light, the pink colour of the tunics deepened by the action of the atmosphere upon the dark blood in the vessels; there were also minute points of extravasation, and dark lines in the course of the venous trunks.

There was a great deal of mucus, and minute portions of the root in the small intestines, especially in the lower part of the ileum.

The state of the heart was natural, but the blood found in it, and also in the great vessels, was very black and fluid.

No trace of decomposition had occurred.

The second body examined was that of Peter Knight (No. 2), which presented similar external appearances, and was thought to be equally livid, but had somewhat less muscular rigidity.

A greater quantity of blood than is usual flowed from the incisions made in opening the head and spine. The principal abnormal circumstances noted on this inspection were the veins of the pia mater very much distended, causing extensive arborescence both on the surface and between the convolutions of the cerebrum. The plexus choroides had a dark damson colour, the velum interpositum much injected, and many vessels ramifying upon the corpora striata. The veins of the cerebellum, at the base of the brain, and the basillary veins, were also in an equal degree distended. The tentorium was extremely blue in colour, not from extravasation, but from great injection.

The substance of the brain in all its parts was more vascular, and exhibited more bloody points in the sections, as did also the pons varolii, medulla oblongata, and spinal marrow. The roots of the nerves were also red from injection; the sinuses of the spinal marrow gorged. About two drachms of serum in the ventricles; four drachms were collected at the base; and there was also general, but not great, effusion under the arachnoid.

A slight contusion on the soft palate had resulted from the passage of the stomach tube, but the whole of the throat, the root of the tongue, the glottis, and epiglottis, were much reddened; the follicles at the base of the tongue were particularly large and prominent. The œsophagus reddened through its full extent; at the lower end the cuticular lining with its fimbriated edge particularly evident.

The glottis and sacculus laryngis were lined with frothy mucus; the trachea most intensely injected of a deep purple almost black colour. The bronchi were similar in colour, and plugged by mucus. The lungs were very dark, extremely congested, and in many places apoplectic effusions had occurred.

The peritoneal coat of the stomach had a pink colour, especially intense about the cardiac orifice. Large black veins were running along its lesser curvature, and branching down its sides. The mucous membrane thickened thrown into large rugæ follicles prominent with vascular apices, and of a pinkish colour, pylorus contracted: there was much extremely viscid mucus strongly adherent. The state of the intestines similar to that described in the last case.

The body of "Wilson" (3) was also examined, and we noted in the head and spine the same appearances.

In the mouth and throat, the papillæ of the tongue remarkably enlarged. In the fauces, pharynx, and larynx, a remarkable vascular lividity, most intense about the epiglottis and soft palate. The sacculus laryngis and trachea contained frothy mucus; the lining membrane of the trachea also highly congested, thickened, and presenting the same characteristic, though rather less distinct, appearances than the others.

There was an accidental effusion of blood behind the œsophagus, and between its tunics at the lower part. The stomach contained a pint of turbid fluid, with some portion of the masticated root. The stomach and intestines both exhibited the same pink colour externally. The bronchi were likewise congested. The lungs were extremely livid; fluid blood and serum freely flowed from every incision. In some parts the congestion was as great as in cases of pulmonary apoplexy. The follicles in the œsophagus and stomach very distinct. There was a

large quantity of viscid mucus in the stomach, especially near the pylorus.

The only difference noted on the inspection of the body of Jones was the presence of a layer of extravasated fluid blood beneath the pia mater covering both hemispheres of the cerebrum. The colour of the membranes was quite blue. The effects upon the other organs were quite answerable to those already related in the other cases.

From what has been related, it appears that the effects which the *œnanthe* produced in these cases were a violent irritation of the mucous membrane of the œsophagus and stomach, more particularly of the follicular structures, and a state of severe and universal spasm of the muscular tissues; it also induced insensibility, coma, delirium, extreme congestions of internal organs, and, in those cases immediately fatal, it occasioned permanent fluidity of the blood.

The first indication of treatment was doubtless to evacuate the stomach; but, as its sensibility was destroyed, and the poison was taken in the solid form, this could not readily be accomplished. Large and immediate depletion seemed to be essentially useful, by removing the imminent danger of extravasation from over-distension of the vessels; the cold affusion was also beneficial in rousing the patient, so as to make him sensible to the emetics, and so were purgatives during the after treatment.

Called thus in a moment to so many urgent cases of poisoning, it became needful to use such remedies as were at hand, but upon reflection it seems to me proper, in similar circumstances, to rely chiefly on emetics given early, on large blood-letting *immediately* employed, and the cold affusion.

Although the attempt to re-establish respiration by tracheotomy failed in the case selected for it, in consequence probably of the great effusion of blood afterwards found on both hemispheres of the brain, yet it is worthy of a future trial in single cases, where it can be more conveniently practised.

Considering the great activity of this poison, that it is capable, as we have seen, of extinguishing the life of a strong young man in full health in *one hour*, and that many other fatal cases are recorded, it is rather singular that the nature of the active principle of the *œnanthe* is not yet well known, or the plant applied to medicinal use.

Woolwich, April 24th, 1814.

ON THE
DECREASE OF DISEASE THROUGH
THE PROGRESS OF CIVILIZATION.

By C. F. H. MARX, M.D.

Professor of Pathology in the University of
Goettingen.

(For the Medical Gazette.)

[Continued from p. 187.]

HYDROPHOBIA is on the whole a very rare disease; in many places it is known from hearsay only*; in others, again, it has undoubtedly its occasional victim†. As all means have hitherto been found unavailing against this disease when once established, there is the greater reason in every degree of precaution that can be taken against it. The prophylaxis of hydrophobia is of different kinds; that in which the bitten part is excised, is, however, the only one that experience suffers us to rely on as in any way effectual. Lap-dogs, and indeed house-dogs of all kinds, appear to be more subject to the disease than the animals that are kept for field sports; and this has led to police enactments in different countries calculated to repress the number of useless curs. In ancient Argos, during the dog-days, the festival kynophontis was celebrated by the public sacrifice of a number of dogs‡. It were no im-

* Heberden, writing after more than forty years' experience, says that he had never seen hydrophobia from the bite of a rabid animal (Commentaries, sub. voc.); and Stieglitz assures us, that during a practice of thirty-six years he had only heard of a single case of the disease.

† From Hoffmann's summary (Prussian Medical Journal for 1835, No. 45), it appears that in Prussia 266 persons had died of hydrophobia in the course of six years; which is at the rate of about 3 per million of the inhabitants.

[The writer quoted, if I remember rightly, ascribes the relatively greater frequency of hydrophobia in the Prussian dominions than in other European states, to the number of wolves that still exist in the countries that form their eastern boundaries. A physician in fashionable practice, like Heberden, might live a century in London without seeing hydrophobia, and the disease present itself there several times nevertheless. Six months seldom pass without a case occurring in one or other of our great metropolitan hospitals. In the year 1842, I find, from the Registrar-General's Fifth Annual Report, that four persons died of this awful disease in the metropolis, the population being reckoned at 1,875,493.—*Eng. Ed.*]

‡ Müller, The Dorians, i. 346.

At Kertch, in the Crimea, there is a gipsy charged with the duty of clearing the streets of stray dogs. He draws a dead dog through the town, and all the animals who approach to look are put to death forthwith. He has 25 kopecks for every head he delivers to the authorities (Demidoff, Voyage dans la Russie, t. i., p. 552, Paris, 1840.)

politic measure to have recourse in these times to some solemnity of the same kind when it seemed that the taste for dog-keeping was getting the better of the common sense of the community, of that consideration for the general safety which ought to be paramount.

Delirium tremens, or the drunkard's madness, must, of course, be viewed as a consequence of the modern art of distilling ardent spirits, an article of which such destructive quantities may now be procured for so small a sum of money, that debasement and self-slaughter may fairly be said to be placed within reach of all. But the disease of drunkenness appears happily to have passed its acmé; the general reprobation of the practice of indulging in intoxicating liquors, conviction of their degrading and destructive effects, and the consequent diminished consumption of these among the educated and wealthier classes, and even, (and that upon moral and religious grounds,) among the labouring orders of the community, all gives us hope that the evil will be still farther diminished, if it do not seem very probable that it will never disappear entirely*.

The tremors and paralyses from which water-gilders and other artizans who use quicksilver in their handicrafts occasionally suffer, have lost much of their obstinacy since the powers of chalybeate medicines taken internally and administered in the way of both were recognized. And then the late discoveries in electro-metallurgy by which almost every article may be silvered and gilt in the most perfect and substantial manner, by means of the galvanic battery, will unquestionably

* The northern nations of Europe have long had a standing reputation for drunkenness. The habit of indulgence is said to be on the decrease in Russia.

[In England, and particularly in Ireland, drunkenness has received a notable check through the labours of the modern apostle of temperance, the Rev. Mr. Maheew. Honour to the man who dedicates his life and his energies to a cause so holy as the inculcation of the innumerable blessings that flow from temperance! In London, great numbers of the keepers of public-houses die of *delirium tremens*. I have attended many to their end from this cause; and could point out several houses where the mistress has had three husbands within ten or twelve years: the husbands drink themselves to death; the widows are prizes for some frequenter of the house, who, once installed as landlord, follows the example of his predecessor, and is by and by laid side by side with him under the sod, when, of course, the widow is again free to choose another helpmate.—*Eng. Ed.*]

lead to the entire rejection of quicksilver in all operations of the kind.

The *painter's-cholic*, or dry belly-ache, is another disease that vouches both for the progress of general knowledge and of medical science. It is much more rare than it was in former ages of the world; and it is also treated when it occurs with infinitely greater success than it used to be. The practice among the ancient Romans to boil the must of their grapes in leaden vessels, and then to add the syrup thus obtained to other wines with a view to preserve them, was in all probability a principal cause of the severe attacks of cholic to which they appear to have been subject. In articles of domestic use tin has now almost wholly superseded lead; in our white-lead manufactories many improvements have been introduced, by which the workmen are protected; and despite the quantity of this article employed by house painters, they are now so well aware of its noxious effects, that they take care, by wearing gloves and washing their hands particularly before they set themselves to their meals, that none of the article shall be swallowed; cases of lead poisoning are therefore even rare among them;—occasion has already been taken to state that if they do become affected, the treatment of the accident is so well understood, that its consequences are not greatly dreaded. A very great improvement in regard to this class of artisans would undoubtedly be the introduction of the *white zinc*, which has been much recommended, in lieu of the white lead, which has hitherto been regarded as the basis of almost every pigment.

Congestions of blood to various organs or systems of organs—to the head, chest, or abdomen, are commonly reckoned among the number of evils which our civilization induces, and that from over-work of the brain, from stooping, and other uneasy positions of the body, from labour carried on in confined atmospheres, from sluggishness of the bowels induced by sedentary occupations, from the use of considerable quantities of stimulating and highly nutritious food, without sufficient exercise, &c. In assenting to all this, we can still affirm that disease induced by these causes is not very formidable, and does not appear greatly to influence the average length of life of the community.

Hemorrhoids is probably the disease of a congestive kind which is most extensively produced by the series of causes indicated; but if the mucous membranes and blood-vessels of the alimentary canal are apt to be more seriously implicated in consequence of our social usages, than in the barbarous state, it is still quite certain that hemorrhoidal affections occur even there; and under any circumstances they are allowed frequently to act beneficially rather than otherwise, and to serve as abating states of repletion, which falling upon other organs might have more serious effects. Hemorrhoids are seldom fatal; and, indeed, when they are habitually troublesome, they can mostly be referred to some taste, such as the constant use of strong wines or ardent spirits, against which true civilization raises her voice as emphatically, as barbarism sanctions the indulgence*. Hemorrhoids have no ulterior influence; they produce no seeds which necessarily germinate and take root in the organism; it lies mostly in the option and within the power of the individual to determine whether he shall continue to be troubled with the inconvenience, or get rid of it altogether.

Stone is one of the diseases that is certainly not so frequent now as it was in former times. The number of operations performed for its relief now by all the surgeons extant, do not seem to equal those that were done by single celebrated lithotomists in bygone ages. Since the habit of tea-drinking has become general in Holland, stone, which a couple of centuries ago was an extremely common disease, has become a very rare one. Half or three quarters of a century ago, stone used also to be exceedingly common in the city of Boston, United States; but the practice of consuming large quantities of punch at all social meetings in that intellectual city, having given place, as in Holland, to the innocent infusion of tea, stone is now a very rare disease. And, then, the treatment of this formidable distemper has certainly been much improved: chemistry has been

* Hemorrhoidal complaints appear to be much rarer in South than in North Germany, in Southern than in Northern Europe generally; and this, apparently, in consequence of the much smaller consumption of ardent spirits in the former than in the latter. In Petersburg, Attenhofer (Med. Topogr. of St. Petersburg, p. 222) informs us, that of four adult males, three will be found affected with piles.

unwearied in its efforts to find solvents for calculi of different kinds; and if all that we could wish has not yet been accomplished, still something has already been done, and it seems almost certain that much more will yet be effected. The discovery of the strong affinity of the earth lithium for uric acid has but just been made, and will certainly prove important. Further, patients are no longer subjected to an operation which necessarily brings their life into jeopardy, that they may be delivered of a calculus no larger than a coffee or a kidney bean; concretions of this size are seized and reduced to fragments in their seat, almost without risk to the individual. Still farther, a procedure by means of gradual dilatation of the natural passages, and without the use of any instrument more formidable than a lancet, has been revived, has been successfully instituted in several instances, and bids fair by and by to supersede the old operation of lithotomy.*

Scirrhus or *Cancer* is another of the diseases which has hitherto either defied all the resources of art, or against which only the most painful procedures, or distressing mutilations, have been held of any avail. The principle of equal pressure, suggested by the ingenuity of a gentleman who to consummate skill in his profession adds the accomplishments of a profound mechanical philosopher—Dr. Neil Arnott—promises to render recurrence to surgical operation unnecessary in the majority of cases. If it will not counteract the fault in the constitution upon which cancerous disease so commonly depends, neither, it is now admitted, does removal by means of the knife of the particular part affected exert any influence of the kind. By preserving the integuments entire, however, for a much longer period than could have been obtained under the old mode of treatment, this new plan of dealing with scirrhus swellings will undoubtedly prolong life; and then by soothing pain, which it does in the most remarkable manner, it renders the use of narcotic and poisonous drugs unnecessary, and so contributes in another way to the comfort and well-being, and general health of the patient. One of the varieties of

this formidable disease, the *chimney-sweepers' cancer*, will probably disappear with the cruel usage of employing children to sweep chimneys.

The class of *inflammatory irritations*, and of *proper inflammatory diseases*, probably presents the variety of character we witness, and meets us so frequently as it does, in consequence of our civilization having spread from the milder climates of Asia and the south of Europe towards the colder and more inclement north. The habits and usages of the land of our nativity are not readily laid aside; and it would even seem that the system habituated to one of the warmer climates of the earth, transported to a colder country, does not begin at once to feel its influences; it is familiarly known, for instance, that the natives of this country who have passed a considerable number of years in India, on returning home rarely feel the effects of the changeable climate of Great Britain for a year or so after their arrival. To look at the fashion of dress which obtains among our women, in the house especially, no reasonable being would ever imagine that we were dwelling in one of the most variable climates in the world, subject to the most strange and sudden alternations of temperature—blown upon to-day by the warm breath of the south, to-morrow assailed by the sharp tooth of the north; surrounded by an atmosphere generally loaded with moisture, and covered by a sky which, for so many days in every year, denies us the sight of the genial sun; and where erysipelas, catarrhs, and rheumatisms are so rife, scrofulas and consumptions so truly indigenous. Still, let us not overlook the truth, in our anxiety that things were better and more reasonably ordered than they are, that here, too, civilization, with her manifold means and appliances,—convenient clothing, commodious houses, regular exercise both of body and mind, by which either order of powers is strengthened,—steps in, and seems to bid defiance to mere climatic influences, and obviously accomplishes infinitely more than could be done by the rude son of nature, dwelling in ignorance and dull indifference: those countries that once constituted the outermost verge of the habitable globe are now centres of the arts and sciences that most ennobles man.

* See the whole of this interesting subject discussed in a work entitled: *On the Treatment of Stone by Means Medical and Mechanical*, by R. Willis, M.D. 8vo. Lond. 1842.—*Engo. Ed.*

The disease which attracted so much attention some few years ago, under the title of *Egyptian ophthalmia*, is nothing more than a severe catarrhal inflammation of the eyes, in which the natural mucus becomes purulent and irritating, and, at the height of the disease, infectious. The ancients were familiar with this disease, and there is no reason to apprehend any thing from its spread, so long as its contagious character is duly kept in view.

Croup, which so lately was the terror of parents, and which, in its virulence and frequency, seemed a product of recent times, the bane of our social condition, the effect of the mode of bringing up our children, has already lost much of its serious character. The experience now possessed of the admirable power of emetics, used at an early period of this formidable disease, to control its progress, enables us to meet it without so much solicitude for the result as we used to feel, and no longer to look on it as one of the evil spirits evoked by the present times*.

Whether civilized communities are more subject to pure inflammations than uncivilized tribes, may fairly be questioned: persons who are well fed have been held more subject to inflammations than the indifferently nourished, because, as it is said, they are more plethoric and excitable; but this is very questionable. Persons in the high health which abundance of wholesome food implies, resist causes of disease that seize upon less robust and healthy individuals, and make them their victims†.

Febrile diseases, whether of an inflammatory or a nervous type, have lost

* The malignant or gangrenous inflamed throat, an old disease, but which was particularly rife about a couple of centuries ago (Sprengel, l. c. iv., p. 486), has become so rare that it now scarcely ever presents itself, save occasionally, and as an exception to the rule, in connection with bad forms of scarlatina. This exudative inflammation of the throat is, however, certainly a very formidable disease when it occurs. The passage in Galen (*De Locis Affectis*, lib. i.) which has been supposed to refer to croup, is extremely obscure.

† Sir Gilbert Blane states that he observed our English sailors to be more subject to inflammations in 1814 than formerly, and this because they were better kept and more healthy. (The passage to which our author alludes (*Dissert.* p. 24) is evidently pure hypothesis. It is certain that diseases of every description have greatly diminished in the Navy. Long voyages through every variety of climate are now performed without the loss of a man.—*ESQ. ED.*

much of their danger and deadly tendency, since their nature has been more carefully studied, and the circumstances that favour their propagation have been recognized, and either lessened in force or removed entirely. The treatment of this class of diseases is also much better understood than it used to be: the insufficiency of the old heroic or very active means of dealing with fever is now admitted; we no longer attempt to subdue the disease; we rather look to carrying the patient safely through the several phases of the malady; and in the majority of instances, under somewhat favourable circumstances, we reckon with confidence on seeing him by and by restored to his former strength and efficiency. The worst forms of fever, too, if met be allowed, are rarer than they used to be: some countries seem even to escape them entirely; in others, however, they prevail with unabated virulence. In the latter case the merit of circumstances, giving them in by so much to the former. Egypt and India appear neither to be the seat of typhus, nor to have any power of propagating its contagion*. India, on the contrary, is periodically ravaged by the disease, and proves a very hot-bed for its production and extension. But it is even here that we obtain a distinct view of what the zeal and devotion of the medical practitioner can accomplish with very little encouragement from government, and even less from the sufferers themselves†.

It is difficult to say wherefore certain countries and seasons have suffered so much, others so little, from epidemic fever. Civilization very certainly has no part in the infliction: all her efforts are, on the contrary, directed to rendering what are presumed to be the causes of fever ineffectual. The ancients have

* Sir J. McNeill, who accompanied the detachment of British troops from India to Egypt during the occupation of the latter country by the French, observed no well-marked case of typhus in Egypt, and in India he never saw one. When the disease broke out in the troops on the voyage out, and raged severely, as the disease did not reach India. When it was brought ashore it never spread. Sir James also, in a second case, never appeared on shore, and on inquiry, I found that no case had ever been known on the western side of the Peninsula, nor have I ever heard of its existence in the eastern.—*Medical Sketches*, p. 169.

† The *Historic Sketch of the Causes, Progress, &c., of the Contagious Fever in 1817*, by W. Harty, M.D., Dublin, 1820, may be regarded as a most excellent information on the present subject in the text.

scarcely left record of their experience in any save the malignant nervous forms of continued fever*. The Arabians were well acquainted with the adynamic or low typhus, and treated it with refrigerants†. But a long interval elapses before we find this form of disease mentioned again; and even in very recent times physicians have been found who maintain that it only made its appearance towards the close of the last century‡.

The *petechial typhus* accompanied with severe head symptoms, or typhomania, is now much rarer than it was in former ages§. The sweating sickness, which occasioned such havoc in England in the course of the 15th and 16th centuries, has either long ago disappeared from the face of the earth, or has a character of mildness which makes it unregarded||.

The remembrance of the Hungarian fever, which presented itself with the nervous putrid character, but accompanied with severe cramps of the stomach, and spreading by contagion, is only preserved as matter of history¶.

* Vide Ochs *Artis medicæ principes de curanda febre typhode*, Lips. 1830; Wawruch, *Antiquitates typhi contagiosi*, Viadob. 1812; Marx, *Origines Contagii*, and Häser's *Historic Pathological Inquiries* (in German), Lips. 1839. Dr. W. Falconer drew a parallel betwixt the *vóros kardiakós*, the morbus cardiacus of the ancients, and the nervous fever of the moderns (*Mems. of the Med. Society of London*, Vol. vi.

† Sprengel, l. c. p. 367, 379, et 396.

‡ Rush, for instance, says (l. c. p. 85): "The nervous fever has become so familiar to us, that we look upon it as a natural disease. Sydenham, so faithful in his history of fevers, takes no notice of it. Dr. Cadwallader informed me that it made its appearance in this city (Philadelphia) about five and twenty years ago."

§ Diseases appear to be ever the same, though greatly modified by the circumstances in which they appear. Some eight, ten, and twelve years ago, most of the cases of continued fever we encountered in the metropolis, and they were rife, were accompanied with an eruption of petechiæ upon the breast. This fever has, in fact, preserved the same type almost up to the present time.—*Eno. Ed.*

|| The epidemics of sweating military fever, which they have had in France upon more than one occasion of late years, were probably of the same nature as our old English sweating sickness; but they differed from it essentially in the small ratio of mortality. (Vide Rayer, *Hist. de l'Epidémie de Suette Militaire qui a régné*, &c. 8vo. Paris, 1822.)—*Eno. Ed.*

¶ In Breslau more than 18,000 persons died of this fever in the year 1758. Süßmilch, l. c. vi. cap. 9. [Camp fevers, and beleaguered town fevers, attend upon every war, and are far more destructive than the swords and bullets of enemies. The mortality of the British Peninsular army is said to have been 36 per cent.; but of this number not one-half—not more than 15 or 16—

Plague, which, under the title of black death, spread like the destroying angel over the face of the inhabited earth in the middle of the 14th century, which in the 17th century committed such fearful ravages in many cities, particularly London* and Vienna, which, in the beginning of the 18th century, swept away nearly one-third of all the inhabitants of Brandenburg, and one-half of those of the city of Dantzic, and which even in these days keeps hovering upon the confines of our European civilization, ready to break in upon us were opportunity afforded it—plague, which has lost nothing of its destructive power, is fairly kept at bay by civilized man†. Whilst the nations to whom the Koran serves as guide in faith and practice sit contentedly looking on at the almost ceaseless havoc which this scourge makes among them, see unmoved how the consuming fire, scarcely quenched, is again rekindled, and burns as vigorously as ever, fed by the old materials; regard it as decreed of unchangeable destiny that they and theirs, the nearest and the dearest to them, should be carried off in crowds; in their infatuation as to consequences, appropriate the goods and chattels of the deceased, and show themselves in the very garments which had been stripped from the victim of plague; and in their treatment of the destructive disease, pin their faith upon mummy, bezoar, amulets, and such other fanciful remedies; Christian nations, on the contrary, use every reasonable measure of precaution against the scourge: they hold no communication with the diseased; they are unwearied in their cleansings and purifications, and, by diet, and the means that scientific medicine indicates, do all that seems right and proper

died from accidents in the field. In the war in Ceylon, under Gen. Brownrigg, when Candy was taken, the mortality amounted to 45 per cent. of the force employed; but not more than half a dozen men were killed by the enemy; fever, on the other hand, slew its hundreds: exposure in a battle of Waterloo is scarcely so hazardous to the common soldier, as a year's quiet residence in the Island of Jamaica.—*Eno. Ed.*

* In the year 1665, 70,504 persons are said to have died of plague; the year after this the great fire of London happily occurred, and since then that great city has known nothing of this pestilence. In 1679, Vienna was nearly depopulated by plague, and Augsburg lost one-fifth of its inhabitants from the same cause in 1685.

† Vide Tully, *History of the Plague as it has lately appeared in Malta, Gozo, Corfu, &c.* Lond. 1831.

to escape; and this with such success that the enemy may fairly be said to be kept at bay. Whilst under our quarantine regulations every attention is paid to the comfort and well-being of travellers and navigators, the safety of the community, being still held the paramount consideration, is never compromised. The most active traffic, both by land and sea, can thus be carried on almost without interruption; for a few days' or even weeks' demurrage is a very small price paid by individuals for the assurance both of their own safety and of that of the nation to which they belong*.

It would even seem as if the unwearied admonitions of more enlightened powers, and the influence of example, were to prevail at last with the Turks, that in the native land of pestilence the voice of fatalism was about to lose its sway, and the dictates of sense and foresight to be listened to, in the establishment of an efficient medical police. The hopes of all the friends of humanity, that the time might come when these ignorant men should participate in the blessings of civilization in gaining immunity from plague, are certainly approaching fulfilment.*

[To be concluded in our next.]

* Gosse, in his remarkable paper on the reform of quarantine regulations, (Biblioth. univers. de Genève, T. xlii., p. 46, et seq. 1842) endeavours to show that a quarantine of a fortnight in reference to plague, and one of six days in respect of yellow fever, are quite sufficient. He expects that the effect of civilization will be to circumscribe in a continually increasing degree the empire of contagious diseases. Leprosy, syphilis, small-pox, and plague, vouch for the beneficial influences of social improvement; they are not now to be compared in point of intensity with what they were in former times. If any one asks, wherefore these diseases have shown a disposition to become more simple, and even to disappear, let him be answered in these words: Because of the influence of civilization and medical science, the progress of reason, and of the healing art. A well-informed writer in the October number of Forbes' British and Foreign Quarterly Review, 1843, is of opinion that the period of incubation of the plague is ten, at the most fifteen, days. It is by no means necessary to look on whole countries as infected because particular places of them are the seat of plague.

† M^r Grigor, in his Sketches (p. 102), has these words:—May we not indulge a hope that as the intercourse of civilized Europe with the countries of which the plague is now the source, becomes more regular and intimate, we may be enabled to extend to them our discoveries and improvements, and so direct them to the means of divesting the plague of its terrors, and reducing the mortality from it to that from fever and the small-pox in Europe?

ON

DISARTICULATION AT THE ANKLE.

(In a Letter to Prof. Syme, of Edinburgh.)

By WILLIAM LYON, Esq.

Lecturer on Surgery, and lately one of the Surgeons to the Glasgow Royal Infirmary.

DEAR SIR,

CONCEIVING that you may be gratified and interested by the details of a case in which, led by your recommendation and example, I lately practised disarticulation at the ankle, I beg to transmit the following particulars, and hope to be excused for thus addressing you.

The operation proposed, if not practised from a very remote period (see *Med. Operatoire*, par Velpeau, ed. 1832, tom. i. p. 476, art. *Amputation du Pied en Totalité*), is not, I think, so perfect as that you recommend: at all events, we are indebted to you for its re-introduction, recommendation, and performance. So far as can be judged from the results in your two operations, and in my own, I incline to the belief that this procedure is less severe in its immediate effects, and consequently less dangerous, than amputation in the lower third of the leg: but, besides, the longer lever which is left after it, enables the patient to move the member forcibly and actively, and to bring into play in the most effectual manner the apparatus requisite in walking: the broad articular surface likewise allows the weight of the body to be thrown on the soft tissues covering the face of the stump, without causing pain or risking ulceration, while farther immunity from the effects of pressure on the same part is obtained by the thickness and density of the tissues forming the flap. For these reasons I have scarcely a doubt but disarticulation at the ankle will frequently supersede amputation in the leg, and become one of our common operations; but as our experience of it is very limited, I hope the additional example of my case, and the circumstances attending its progress, may, through you, be useful to other operators.

The patient, who is 20 years of age, was under my care in the hospital while I was lately acting as surgeon. He entered with incipient strumous osteitis of the anterior tarsal and metatarsal bones of the right foot. The affection advanced, in opposition to all the usual practice, and he was dismissed

with a recommendation to reside in the country. He called upon me about seven months since, reduced in strength, his health much impaired, and the disease in the stage of caries, probably with morbid deposition. The os calcis and astragalus being, to appearance, sound, Chopart's operation was proposed, but was declined. The patient returned a month ago—having, in the interim, most assiduously used the cold-water cure! the disease aggravated, the os calcis and astragalus involved, and the health and strength farther impaired. He was now willing to submit to any thing. But Chopart was of course out of the question; and having always, in amputations of the upper and lower extremities, operated as low as possible, in order to obtain the smallest wound, and the most serviceable stump; taught, in addition, by your experience and recommendation, and by my own observation of the effects of amputation in the wrist and elbow; I determined, as the extremities of the tibia and fibula seemed unaffected, to disarticulate at the ankle.

Guided by your precepts*, the operation was easily and quickly executed. The cartilage covering the tibia was healthy, but the malleolar processes were so soft as to excite the fears of some of my professional friends present. Similar conditions of bones are, however, common in strumous subjects; and the result has shewn that the alarm in this instance was groundless.

Convinced of the propriety of the step by your reasoning, I made, as a *safety valve*, an opening at the most dependent part of posterior flap; dressed with a few strips of plaster, and, as I have usually done after amputation, applied cold lotion over the wound.

Scarcely any local disturbance followed the operation; indeed I never saw less, if so little, after an amputation of such extent; the general condition was equally favourable with the local.

Upon dressing on the fifth or sixth day, I found about a finger's breadth of the anterior margin of the posterior flap dead, and saw that adhesion had not any where occurred. The dead portion soon separated, the discharge was healthy and in small quantity, granulations sprung from the synovial membrane covering the granular cartilage, and from the cellular membrane or in-

side of flap, and the two surfaces soon united. The patient rapidly improved, was out of bed in fourteen days after the operation, and but for the raw surface left by the loss of margin of the flap, would have been quite well a week since; had the want of strength not prevented him, he at this time, twenty-five days after the operation, would be, with aid of crutches, taking exercise in the open air.

With all this, I think there are some objections to the operation, which, however, may probably be obviated by attending to certain particulars. I think I erred in applying cold lotion to the wound; I am satisfied that the propriety of this practice, after amputation by the circular method, may reasonably be questioned; for the flap, composed only of skin and cellular substance, and much separated from its connections, has its circulation diminished by the cold, and it may, by the same cause, be entirely arrested. In this operation the flap is larger, and still farther detached, than in amputation by the circular method; the application of cold is therefore still more hazardous, and should never, in my opinion, be employed; it ought to give place to means for retaining or supplying heat, as carded cotton or the warm-water dressing.

There is another cause for the sloughing of the anterior margin of the posterior flap, which occurred in one of your patients, and also in my own: the posterior flap is very large, and the condensed cellular substance and thick cutis composing it are not very liberally supplied with blood; being separated from all its subjacent connections, it can only receive circulation from the vessels that pass through the skin and cellular substance of the posterior and inferior part of the leg, to which it is alone attached; the circulation in vessels so much insulated, and running so far from their origins, as those in the flap, being consequently weak, must needs be liable to be altogether interrupted.

To meet this objection, I think more than usual care should be taken to place the margins of the anterior and posterior flaps in *close, easy, contact*, so that, union by the first intention occurring, blood from the vessels of the anterior will pass into those of the posterior flap, and thus its death be prevented. This is the more requisite, since immediate union between the synovial membrane covering the car-

* Edinburgh Monthly Medical Journal, Vol. III., 1843, p. 28, 274.

tilage, and the condensed cellular membrane lining the flap, is not to be expected. The same reasons which urge us, in our efforts to obtain immediate union, to recur to the cautious employment of sutures and plasters, enforce the avoidance of pressure over the flap; therefore the propriety of not employing compresses or bandages.

So much was I impressed with the risk of losing the flap from the cause above mentioned, and also with the difficulty of easily forming it, that I was much inclined to have operated by two lateral flaps: this mode would certainly facilitate the performance of the operation, but would sacrifice the thick, dense tissue obtained from the heel,—one of the principal advantages of your method.

To insure, as far as possible, the success of this operation, it will be advisable to keep the cut edges of the flaps in *close, gentle*, apposition, by interrupted suture and short strips of plaster; to promote the flow of blood into the flap, by supporting its temperature with carded cotton, warm water dressing, or the like; and, in order to secure free discharge of secretions, to make, as recommended by you, a fair dependent opening in the posterior flap. This latter point will be the more necessary if the close approximation I have suggested be adopted.

Yours most respectfully,
W. LYON.

Glasgow, May 30th, 1844.

To Professor Syme.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

Caloric: its Mechanical, Chemical, and Vital Agencies in the Phenomena of Nature. By SAMUEL L. METCALFE, M.D. of Transylvania University. 2 vols. pp. xix. and 1100. Pickering.

(Second Analytical Notice.)

WHEREFORE are the men who are in advance of their age so commonly poor and unregarded? wherefore, neglected and unknown, do they so constantly die broken-hearted, before their time? For the simple reason that they are not of the day in which they live, and cannot be understood by their contemporaries; they bring new commodities

into the market, for which there is as yet no demand. Demand, however, in the world of matter, is the acknowledged grand creator of supply; although supply of aught that can be turned into use will also, it is said, create demand; but this is only by and by. It is the same in the world of mind: we all belong to our age, and identify ourselves more or less completely with prevalent tastes, and current fashions, and the ordinary literature of the day. The caterers of this literature are of ourselves, of the day; they have but a small sprinkling of individuality, of originality; they are of necessity ordinary men. If they have a larger infusion of the divine fire in their composition than usual, they are not esteemed at first, and the time during which they remain unnoted is in proportion to their deserts: a Milton has to wait a century or so to have his merits admitted; a Shakspeare, as the merit is higher, has to wait hard upon two centuries; and so on, and in reference to every thing else.—James Watt makes an application that is to change the prospects of society over the face of the whole habitable globe, and he has to petition for an extension of the period of his patent, that he may escape bankruptcy and ruin, &c. &c.

This business of critic which we have in hand we feel to be indeed a high and a responsible office; it presents itself to us almost with the same amount of sanctity as did Milton's sublime subject to his god-like mind, when he said that it was “not to be raised from the heat of youth, or the vapours of wine, like that which flows at waste from the vulgar pen, nor to be obtained by the invocation of dame memory and her siren daughters, but by devout prayer to that Eternal Spirit who can enrich with all utterance and knowledge, and who sends out his seraphim with the hallowed fire of his altar to touch and purify the lips of whom he pleases.” We cannot change the constitution of society, but we can escape the familiar sin of neglecting genius, of scouting and contemning that which is, in truth, in advance of the day in which we live; and so we return to Dr. Metcalfe's work upon *Caloric*.

“The whole object of medical science,” says our author, “is to regulate the forces of life,—to increase them

when they are deficient, to restrain them when excessive, and to restore their natural balance when deranged. But how can we know the right means of maintaining the functions of life in a healthy state while ignorant of the physical cause on which they all depend. Why are so many diseases pronounced incurable, but that we know not what causes the heart to beat, the stomach to digest, the brain to think, the nerves to feel, and our active limbs to move?

"The true panacea, or elixir of life, must not be sought in specifics and nostrums, but in a clear and definite knowledge of the mode in which the organizing principle operates in the different functions of life. Were it not that all the phenomena of nature are linked together as parts of one great whole, it would be of far higher importance to know the cause of vital, than that of planetary motion. Nor was it ever intended by Infinite Wisdom and Goodness, that knowledge so essential to the happiness of our race should remain a sealed book. Life is the problem of problems, the solution of which would clear up a thousand other mysteries, and banish innumerable errors from the pages of science. And it may be asserted with confidence, that whoever is without faith in the power of well-directed efforts to resolve it, will never accomplish much towards enlarging the empire of man over the numerous evils by which he is surrounded. A complete knowledge of this subject would do more to elevate the condition of mankind, than the power of transmuting the baser metals into gold, or charcoal into the precious diamond; for all the riches of the earth are not to be compared with health." And again—

"But, unfortunately for the best interests of the world, an impression has long prevailed, that the animating principle is something beyond the powers of the human mind to comprehend. That such a dogma should have been inculcated by the founders of narrow creeds, and individuals interested in keeping the people in ignorance, is not to be wondered at; for in all ages of the world, the empire of imposture has been founded on pretended mysteries, and upheld by ignorance. It is, however, melancholy to reflect, that philosophers should have

given countenance to this prejudice. Enslaved by ancient errors, even the wise Socrates is said to have thought it dangerous, unprofitable, and not acceptable to the gods, for men to pry into the hidden mechanism of nature. And in an article on Life, Voltaire, a professed champion of free inquiry, asserts, that 'the cause of animal motion like that which determines all things to a common centre, and the needle to the pole, is the secret of the Deity.' The general adoption of this opinion by the instructors of mankind, has done immense injury to the cause of science, by discouraging the efforts of genius to press forward into the undiscovered regions of truth; while it has fostered ignorance, indolence, and every description of quackery. If there be any primary and efficient cause of vital force, it must be either a portion of the air we breathe, or of the materials by which we are nourished; and if so, there is no good reason why it should be more mysterious than any of the other phenomena of nature."

From the remotest ages of antiquity men seem to have regarded fire or heat either *per se* as the organizing principle, or, under this symbol, to have adored the Deity, and held it as the agent he employed immediately in his creations. The sun and fire are, in fact, felt by the mass of mankind at the present day as the most apt symbols of the Author of the Universe. In the Old Testament, Jehovah is frequently represented under the brightness of the sun: "He clothes himself with light as with a garment," &c. The noblest heroic poet the world has seen, even speaks of the Deity as light:—

Hail, holy light, offspring of heaven first-born,
Or of the eternal coeternal beam,
May I express thee unblamed? Since God is light,
And never but in unapproached light
Dwelt from eternity, dwelt thou in thee,
Bright effluence of bright essence increate.

In the temples of ancient Persia, fire was kept burning for ever on the altar*; so was it in the temples of Vesta among the old Romans; and it may be seen at the present hour in Jewish synagogues, and in Roman Catholic Christian temples,—greatly reduced in quantity, shorn of its splendour indeed, and not understood of the vulgar; but the

* As the symbol of Deity, according to Hyde, *Religionis Veterum Persarum, Historia, passim*. 4to. Lond. 1760, but this seems very doubtful.

symbol of the Godhead—the legacy of our forefathers of 4000 or 5000 years ago, to us their children of the passing day. In short, elementary fire, from the dawn of civilization to the commencement of the Christian era, had still been the object of especial reverence among men. All the *Dii majores* of antiquity, and even many of the *Dii minores*—Osiris, Jupiter, Apollo, Hercules, &c. are but so many names for the sun, elementary fire, or the active principle in nature. Isis, Juno, Diana, Demeter, &c. again, are but so many titles for the passive principle; as Oromazes, Bacchus, Apollo, &c. are titles of the good principle, and synonymous with light and vivifying heat; whilst Ahrimanes, Pluto, &c. are titles of the evil principle, and of the same import as darkness, cold, destruction, and death.

Elementary fire, then, the ancients appear to have been unanimous in regarding as the active principle in nature, as the physical cause of life. These lines of Virgil have been often quoted:—

Principio cælum, ac terras, camposque liquentes,
Luculentemque globum lunæ, Titaniq[ue] astra,
Spiritus intus alit, totar[um]que infusa per artus,
Mens agit at molem, et magno se corpore miscet.

which our friend Iambus, at our request, translates for us thus literally:

First heaven and earth, and ocean's liquid plains,
And the moon's bright orb, and the Titanian stars,
Are fed by intrinsic spirit,—deep infused
Through all, mind actuates and mingles with the mass.

Mind and elementary fire, or the common actuating cause, were therefore viewed as identical by the ancient philosophers: “Ὁσπερ δὲ ἡμῖν ἀπὸ ψυχῆς διοικούμεθα, οὕτω καὶ ὁ κόσμος ψυχὴν ἔχει τὴν συνέχουσαν αὐτόν, &c. as we are governed by a soul, so the universe, too, hath a soul, by which it is contained; καὶ γὰρ αἱ ἡμέτεραι ψυχαὶ κύρ εἰσι— and our souls also are of the fiery element*.” And see how another of the philosophic writers of antiquity, Sallust the philosopher, the cotemporary of Proclus, expresses himself: — Αἱ δὲ καρτερὰν—but we shall translate: “But the souls of those who have lived virtuously, remote from all that is irrational, severed and purged from the body, are conjoined with the gods themselves, and with them have part

in the government of the universe*.” This is surely a grand and ennobling view of the destiny of the soul after death.

Descending to more modern times, we find all the distinguished writers of the sixteenth century admitting the existence of an active principle in nature as the cause of motion and organization. Harvey appears to have been very near what our author holds to be the truth, when he indicates the *calidum innatum* as the immediate cause of vitality in the blood, and of the action in the heart; the *archæus* of Paracelsus and Van Helmont was but another name for the *πῦρ æσπορ* or intelligent fire of Pythagoras, an element universally diffused and operating with consummate intelligence in the formation of all things. The *pneumatical body* of Bacon is something of the same kind, it is the *πνεῦμα*, synonymous with the *αἰθήρ* of the Greeks, whence *æir*, air, from *or*, or *ur*, light, which particle pronounced on the lips becomes *πῦρ*, and the *p* changed into *f*, the word is Feuer German, fire English. The vital, natural, and animal spirits of Descartes, did not differ from the *πνεύματα* of the Greeks. It was not in fact till after the special inquiries of Willis into the anatomy of the brain and nervous system, that the various functions of life began to be referred to the influence of an imaginary principle, which was held to be prepared by the brain, and conveyed to all parts of the body through the nerves—the *nervous fluid*, the *vital* or *animal spirits*. Following Hoffman, from whom he borrowed largely, this doctrine was espoused by Cullen, and made the basis of his speculations on the nature of disease; and through the strong hold he had upon the Edinburgh school, and the eagerness with which the physiology of the nervous system has been cultivated of late years, this may be said to be the fashionable doctrine in these countries at the present day. Greatly influenced in his physiological views by the neurologists, Haller referred all the phenomena of life to irritability and sensibility, the first being assumed as an inherent property of the muscular fibre, the other of the nervous masses. Mr. Hunter is nowhere very clear upon the principle of life; he sometimes speaks of it as an

* Phuranti, de Natura Deorum Com. In Opusc. Mythol. a Tu. Gale, Anglo. 8vo. Amst. 1668.

* De Disi et Mundo, Opusc. Mythol. à Gale, p. 279.

independent entity under the title of *materia vitæ*; but then he seems to confound it with the hypothetical nervous fluid, and sometimes even with the nervous matter. He says, "something similar to the materials of the brain is diffused through the body, and even contained in the blood; in another place he mentions the stomach as the seat of the *materia nitæ*; finally, he says, "life is a property we do not understand." Mr. Abernethy, also, in avowing that in the then unsettled state of knowledge he could not advance a step farther than Mr. Hunter had led him, still fancied that the *materia vitæ* of Hunter might be referred to *electricity*; and such was his influence that at one time it was held little less than impious to doubt that it was so. Other, particularly French, physiologists, have thrown over-board the idea of an animating principle altogether. "Life is the result of all the organic forces," "the sum of the functions that resist death," "the assemblage of the properties and laws that govern the animal economy." But such language is a meaningless jargon; properties, laws, and powers without any source are referred to;—a superstructure is raised without a foundation; effects are indicated without a word of their causes. It is obvious, indeed, from the preceding sketch, as Mr. Whewell has but too justly observed, that we are at the present moment "without any genuine physiological principle, and have yet to learn all that we are to know concerning the ultimate laws of organized bodies."

Every onward step we take in knowledge shows us more clearly than ever that all the operations of nature are so intimately connected, that it becomes finally impossible to draw a strict line of demarcation between physical, mechanical, chemical, and vital actions. Our author has shown caloric an idio-repulsive, a self-moving agent, and then he has demonstrated it as the cause of motion in all things else: the mechanical force of steam is generated by the chemical union of caloric with the particles of water; the ascent of the sap of living vegetables is no less the result of attraction than the rise of water in the pores of a sponge, or in the capillary tubes of glass rods; the first process in the germination of a seed, the first step towards the production of a new being, is of a purely chemical

nature: a portion of its substance is converted into sugar and gum with the evolution of carbonic acid and the disengagement of caloric. Still ascending, the digestion of animals is indubitably a chemical operation: we can have it performed almost as perfectly in our laboratories as in the stomachs of living creatures; and that caloric is a principal agent in the process appears plainly from the fact that digestion is rapid exactly in proportion to the mean temperature of the animal in which it is observed: more rapid in birds than in mammalia, it is accomplished with extreme slowness in amphibia and fishes, among which, days, or even weeks, are required to digest a single perhaps somewhat copious meal; but even here the business is accomplished more speedily in proportion as the temperature of the surrounding medium is more elevated, and that of the animal which inhabits it is high. And it is not otherwise in our laboratories: the gastric juice is altogether inert, has no power of dissolving anything, at a temperature between 30° and 40°, or even 50°, in the higher animals; but at 100° Fah. it dissolves and converts food into chyme as perfectly, if somewhat more tardily, (for which very satisfactory reasons can be given) as if it were still contained in the stomach. —Chemists seem, by common tacit consent, to overlook the influences of the heat they employ so universally in their processes—the spirit-lamp, the chaffeur, and the furnace, are never reckoned for much in the business; they are matters of course rather than of necessity, and without whose agency almost none of all the decompositions and recompositions that take place, could be effected.—Finally, the all-important function of respiration, the very beginning of life in the more perfect animal, is a purely chemical process: a portion of the oxygen of the lifeless air unites with a portion of the lifeless carbon and hydrogen of the blood, caloric is evolved, the cause of motion is obtained in adequate quantity, and all the phenomena of vitality, varied, multiplied, according to the complexity of the organism in which they are manifested, ensue.

And truly it seems to us that this is obvious and undeniable: the amount and activity of vegetable life throughout the earth is evidently in proportion to

the heating power of the sun : greatest under the equator, it diminishes gradually from the tropics to the arctic and antarctic circles ; temperate latitudes, with their varying seasons, are evidently altogether dependent on the presence of the sun for any effectual manifestation of the vegetative force. Who that has looked on the earth in the winding-sheet of winter, and seen her starting instinct with life on the return of spring — whose sole appreciable difference from winter is its higher temperature — and, under the eye of the bright sun, clothing herself with beauty, renewing her species, and, out of alternate death and reascitation, presenting us with a picture of immortality, who, we ask, will doubt that heat is the vivifying element in the scheme of vegetable creation at least ? Nor is the law different in regard to animal life : genera and species of animals are alike abundant within the tropics ; they are few and thinly scattered towards the far north and extreme south, where the world of air-breathing insects disappears, and the mammiferous animals and birds that are encountered, live and brave the rigours of the climate, in virtue of the powerful calorific apparatus they bear about with them in the shape of ample lungs, and the thick coat of fat, or fur, or feathers, by which their engendered caloric is economized. Coming down to particulars, do we not farther see that the aggregate vital energy of animals is always in proportion to the activity of the respiratory process ; in other words, to the amount of caloric which they obtain by this means from the atmosphere ? And, again, do we not see that no seed ever germinates, that no egg is ever hatched, without a due supply of caloric ? And, still farther, that the product of this seed, of that egg, unless it derives a certain measure of heat from the high temperature of the surrounding medium, or its parent, or has the power of engendering this within itself, languishes, droops, and dies, “are we not forced to conclude,” says our author, p. 532 and 541, “that the cause of vital manifestation is a constituent of the atmosphere, a portion of nature, and not a hyperphysical essence, as supposed by modern theorists, who have confounded the physical cause of animal motion with sensation, volition, and thought,

which are operations of the nervous system, and not material entities ?”

But the dependence of vital manifestation on the atmosphere, and even on a single principle of that atmosphere, viz. oxygen, being admitted, the whole question of the efficient cause of life is brought within a very narrow compass ; we have only to ascertain whether oxygen produces its wonderful effects, in the world of organization, by its immediate agency, or by the evolution of an imponderable fluid in the course of its combination with some principle of the body, to have ascertained the truth, to have penetrated the mystery of life. Our readers will of course divine how Dr. Metcalfe decides this question : the oxygen of the atmosphere is instrumental in maintaining life by combining with the carbon and hydrogen of the blood, and parting with its latent caloric in the act. “But,” says our author in continuation, “if the number, diversity, and specific character of plants throughout the earth, be determined by the amount of caloric derived from the sun, it follows, *a fortiori*, that the vital force of animals, and the development of their organisms, must be regulated by the quantity of the same agent which has been shown to be the active principle in light, electricity, oxygen, and all the other forms of matter.” Higher in the scale of creation than vegetables, animals, as they are more perfect, are less and less dependent on the free heat of the atmosphere ; and having attained to a certain grade of completeness, their power of extracting its combined or latent heat is such that they virtually cease to depend at all upon its sensible warmth ; they disengage *vital fire* from an atmosphere that renders quicksilver solid.

This brings us naturally, along with our author, to consider the function of respiration, avowedly the first and most immediately connected with life of all the processes that take place in the animal organism ; so immediately and so obviously, indeed, that Moses says : “God breathed the breath of life into the nostrils of man, and he became a living soul.”

Nothing can give a more woful picture of the state of physiological science than a review of the opinions that have been current up to the present hour,

first, upon the end and import of respiration, and then in regard to the precise source of animal heat. The ancients, and likewise the moderns, up to a very recent date, believed that the end of respiration was to cool the blood; Black and his contemporaries, Crawford, Lavoisier, &c., taught, on the contrary, that its purpose is to evolve heat in the same way as heat is evolved by the combination of oxygen with ordinary combustible materials; but by and by Sir Benjamin Brodie was led to infer that heat was, in some unexplained way, generated by the nervous influence. Philip maintained that it was the result of secretion; Tiedemann that it depended immediately on the process of nutrition; Mr. Mayo ascribes animal heat in one place to nervous influence; in another he says its source is unknown; Dulong and Despretz reverted to the old doctrine of Black, only in part however; for whilst they allow respiration as the principal source of animal heat, they believe that another portion is extricated from the blood by nervous influence. Müller, coming after them, reverses the order, and maintains that the reciprocal action between the organs and the nerves is a main source of animal heat; and Dr. Southwood Smith, writing but a few years ago, and representing general opinion rather than his own on the subject, says that "whether the blood acquires something from the atmosphere which is essential to life, or parts with something incompatible with life, is wholly unknown!"

Even among the physiologists who acknowledge respiration as the source of animal heat, it is undecided whether the combination between the oxygen of the air and the carbon and hydrogen of the blood takes place in the cells of the lungs, as taught by Black and his followers, or in the course of the general circulation, according to the prevailing or current opinion. In such a state, we dare not say of *science*, but of *ignorance*, we can hardly wonder, with our author (p. 542), that "no systematic attempt has yet been made to connect the theory of animal temperature with the laws of life." The purpose of Dr. Metcalf, as our readers will have presumed, is to do this, and the manner in which he sets about it is indeed masterly. He first inquires into the

precise point at which the principal amount of combination between the oxygen of the inspired air and the carbon and hydrogen of the blood, with the consequent evolution of caloric, takes place; and this he shews to be the lungs, upon the strength of the simple fact, first demonstrated by Dr. John Davy, that the blood in the left ventricle of the heart is from 1° to 3° ; probably, in health, it is always about 3° F., higher than that in the *venæ cavæ* and right ventricle. The lungs are, in fact, the hottest organs of the body, which Dr. Black had inferred they should be, but which Cullen treated ironically, actually announcing the truth as an absurdity: "If animal heat were the effect of respiration," said he, "the lungs would have a higher temperature than other parts of the body." And so they have: the blood in the right side of the heart of a spaniel bitch, Dr. Davy found 104° F.; the pleura and the blood of the left ventricle indicated 107° F. This difference between the temperature of the arterial and venous blood is probably the most important fact in animal physics, and it happily now stands in no need of farther confirmation. Dr. Metcalf's application of the fact is wholly his own. He believes that the end and influence of the caloric obtained by the blood, in the course of the lesser circulation, is to cause it to unite with and nourish the solids of the body, and so enable them to manifest their special properties: hence vital manifestation of every kind; hence, but with the very important addition of the cause, "life, as the sum of the forces possessed by living beings" of the French school. In the course of the union thus indicated, the caloric obtained from the atmosphere is transferred to the solids from the blood, which loses its bright vermilion colour, and its power of stimulating the organs, until it has regained the crimson hue along with a new quantity of caloric in the lungs; and it certainly is a remarkable fact, which most of us, as practical men, must have noticed, that the blood let from a vein in cold weather is always much darker in colour than it is when the temperature is high. Davy observed particularly that venous blood in the tropics was nearly of as bright a crimson as arterial blood, and Crawford, long before, had

found that the venous blood of a dog, placed in a bath at 114° F., could scarcely be distinguished from that of a neighbouring artery. Here is a new explanation of the difference of colour between arterial and venous blood, one of the many vexed questions in physiology at this time.

Upon this striking and indubitably important basis, Dr. Metcalf now proceeds to shew that the mean temperature of animals is, *ceteris paribus*, directly in proportion to the amount of their respiration, and that the activity of their several functions is in the direct ratio of their temperature. Birds will consume from 1-20th to 1-10th of their weight of solid food per diem, the fox-hound about 1-40th, the race-horse from 1-60th to 1-70th, man about 1-100th of his whole weight of solid nutriment in the course of the twenty-four hours; and the consumption of oxygen, standard temperature, and amount of physical energy displayed, are in the same order; for the food of the animal is neither more nor less than the coke that feeds the furnace of the steam engine, just as the steam raised and power developed are precise indications of the quantity of fuel consumed. Descending in the scale, we observe reptiles, with their vesicular lungs of comparatively trifling superficies, their moderate consumption of oxygen, their low temperature, their tardy digestion and capacity to endure long fasts; and then we come to fishes, molluscs, &c., where gills supply the place of lungs, and in which the amount of vital energy displayed is progressively less and less.

Our readers will have already perceived upon what an extensive series of data Dr. Metcalf generalizes—how ample the store of learning which he brings to bear upon this, as he does upon every other point of his subject; for, indeed, we have followed him very closely in our analysis, and at every step felt more puzzled to select illustration from the abundance with which his pages teem, than seen ourselves forced to look about for further matter of our own. For the acute, lively, and still candid style in which he criticises his predecessors in the path of physiological inquiry, we must refer to the work itself, which is no less remarkable for its candour than for its learning, its taste, and its ingenuity. We had hoped

to have found ourselves with room to touch upon one or two of the pathological topics handled in this interesting work, but must defer this to another opportunity. We conclude this notice by extracting a couple of paragraphs which convey, in brief, a fair specimen of our author's manner as well as matter.

"Whenever the temperature of warm-blooded animals is reduced 20° or 30° below the natural standard, by surrounding them with ice-cold water, the blood loses its florid hue, the surface becomes purple or livid, the action of the heart languid, the secretions are arrested, the brain refuses to perform its office, and the voluntary muscles are seized with spasms, or become paralytic, without the loss of oxygen, electricity, or any other agent, except caloric; and if kept long in this situation, the heart ceases to beat, the crimson tide of life to run, and all the powers of motion are at an end. The graceful form of the rounded limbs is exchanged for sharp or prominent angles, the cheeks become pale and shrunken, the lustre of the speaking eye is gone, the brightness of fancy is quenched, and the "thoughts that wander through eternity" are lost in the night of death."

"If then it be true, that the quantity of life throughout the earth be in proportion to the heating power of the sun, what, I repeat, is the use of animal heat? Is it not the essential character of a *vera causa*, that its power should be in proportion to the effects it produces, and that the latter should cease in its absence? Is it philosophical to assume the existence of any more causes than are sufficient to explain the phenomena? Or if an immaterial and unknown principle of life be still admitted, will it explain anything in the absence of caloric? It is impossible to blink these questions, or to resist the conclusion they naturally force upon the common sense of every unbiassed mind, that caloric is not only the cause of all excitement, but directly or indirectly, of *excitability*—that it is not only the most potent and universal stimulant in nature, but the cause of *stimulability*."

MEDICAL GAZETTE.

"Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri; potestas modo veniendi in
publicum sit, dicendi periculum non recuso."

CICERO.

HOW IS THE STUDENT OF MEDICINE TO ACQUIRE THE INDISPENSABLE KNOWLEDGE OF THE SCIENCE AND PRACTICE OF HIS PROFESSION?

SOME have held that ability to pass the prescribed examination is the only test of fitness requisite. We think them gravely in error. We have already shown that the amount of information necessary to pass the prescribed examination can be acquired by any young man of somewhat apt natural parts, in from three to six months. This is notorious; it is done every day. That the medical student has long been remiss in his attendance upon the prescribed courses of lectures, has always been well known to the Court of Examiners of the Apothecaries' Company. In their lately published Address they refer to the Preface of their Regulations issued in September 1830, in which they say:—

"The Court of Examiners have too much reason to know and lament, that notwithstanding all their precautions, the attendance upon Lectures, and more especially that upon Hospital Practice, is often grossly eluded or neglected; and they deem it their duty to express a hope that the teachers of the various branches of medical science, with whom the correction of this abuse must principally rest, will turn their attention to the removal of an evil of such magnitude. It would be competent for the teachers to insist upon periodical signatures from their respective classes, proving that the pupils are actually in attendance; and it would be equally in their power entirely to withhold certificates from those who have neglected their attendance, or to qualify the testimonial in such a manner, that the Court may apply to those who have been negligent that degree of rigid scrutiny which the justice of the case might appear to demand."

Aware of the fact to which they

allude, the Apothecaries' Company would have done well had *they* taken effectual steps towards securing the presence, at the prescribed lectures, of the young men who were by and by to become candidates for their license: it is quite certain that the lecturers cannot do so. Lectures, as means of instruction, being approved, attendance on them ought plainly to be assured; not being held necessary or preferable to other methods of acquiring knowledge, attendance on them would of course be dispensed with. It seems certain, however, that any competent knowledge of medical science can only be acquired by long years of devotion to its study; even as new garments cleave not to the wearer but by force of use, so do the import and bearing of the facts and phenomena that pass in review before the eyes of the medical student only find their interpretation and application after his mind has been long familiarized with them, after it has assimilated them, as it were, and made them part and parcel of itself. It is that leisure may be had not merely to collect and store up the information necessary, but to digest it properly, that three, four, or even five years are acknowledged to be not too many for the acquisition of the elements of medical lore. The father of physic begins one of his immortal works by lamenting the brevity of life in contrast with the extent of science—*Ὁ βίος βραχύς ἡ δὲ τέχνη μακρά*—Life is short, art is long! He evidently thought differently on the subject of medicine from the young men of the present day, who very generally act upon the presumption that the whole body of the science medical may be acquired in three or four months.

Truly it appears to us that there is no more pleasant or effectual way of acquiring the rudiments of any science than by attendance on lectures. Information is, in this way, imparted

gradually, just as it ought to be; it is also imparted pleasantly—that is, if the lecturer be fit for his business: a very important consideration. Lectures, in the main, and with the public at large, are decidedly popular. We see the great theatre of the London Institution constantly crowded with something like 1000 persons, and that of the Royal Institution with about half the number, all hanging with open ears and understandings on the words and acts of the lecturer.

There is nothing in the system of lecturing, therefore, that is objectionable in itself; on the contrary, there is every thing to recommend it. But it is unquestionable that there has long been a growing indisposition on the part of medical students to attend lectures; they have long given their presence grudgingly; and in the generality of our London schools, with some few exceptions, not more frequently than would just secure them the signature of the professor to their schedule. They have set no store by the information they might have obtained in the class-room.

But this is not all: the student has not been alone remiss; there has also been an increasing indisposition on the part of lecturers to discharge their duties in the chair with energy and good will: the disgust both of pupil and teacher may fairly be said to be mutual. Wherefore is this?

The reasons are various. In the first place, according to the prevalent custom, the young man destined for the medical profession has hitherto been apprenticed for five years to a general practitioner, with a view, as his parents and guardians imagine, to his becoming master of the elements of the art and mystery by the exercise of which he is afterwards to take his place in society, and gain his bread. This was a fatal error, and one of the grand sins

which the Apothecaries' Act of 1815 perpetuated—against the will and inclination of the Worshipful Company, be it said to their credit, but in deference to the opinion of a reverend prelate in the House of Lords, who, we must presume, imagined that the science and profession of medicine and surgery were to be learned, like the handicraft of cabinet-making or shoemaking, under the eye of a competent master. The young man destined to recruit the ranks of the general practitioner, however, has, up to this time, had to serve a five years' apprenticeship; and here began the mischief in reference to him. Taken away from school at the very time when his presence there was of highest importance; indifferently furnished, as yet, with the key that would unlock any treasury of knowledge; removed from wholesome discipline and the necessity of being at least in the way of learning something; the taste for true knowledge scarcely yet awakened in him, he is placed, with a large amount of liberty, and with little or nothing to do, in the surgery of a country apothecary, to get through the lazy hours as he best may, and to contract habits of idleness that influence his fortunes to the end of his life.

The term of five years, however, to be spent in the menial drudgery of compounding medicines, was too monstrously absurd to be generally enforced; there was commonly a compromise between the master and the apprentice, by which, at the end of three, often not till the lapse of four, of the five years, the latter escaped from his Castle of Indolence, literally to *commence the study of his profession*. Whatever may be said to the contrary, it is undeniable that the three or four years of his precious life which he had passed in the surgery, are irrevocably gone, lost to him for ever; and that in-

stead of having learned aught that can ever be of essential use to him in after life, he has, almost of necessity, contracted habits of inattention and of idleness, that unfit him to pursue effectually the course of study that is required of him. More than this, he has, in fact, no longer the time that is indispensable for the purpose: within eighteen months or two years his apprenticeship will have expired, he will be of age, and his relatives and friends expect that he will then be ready to pass his examination at Apothecaries' Hall, and be in a condition to take his place in the world, and do something for himself. In the brief interval of two years, or *two* years and a half, therefore, the student has to crowd attendance upon all the courses required. Such incessant application, however, particularly with his previous habits, he soon finds irksome, distressing, distracting—it may be, impossible; anon he finds out that he can have his schedules filled up by attending occasionally, or even without attending at all; finally, he makes the discovery of discoveries,—that of the modern invention of grinding, by which, in virtue of four or six months*—according to the degree of his previous inattention—of uninterrupted application at the end of his time, he can provide himself with responses to all the questions that can be asked at the Hall or College: this suffices him, and forthwith he begins to lead a jolly or an idle life until the day of trial comes round.

The student then and thus is paralyzed. But his apathy is not confined to himself; it is communicated to his teacher. The disgust both of medical student and teacher, in more than one of our medical schools, may, as has been stated, fairly be said to be mutual. The teacher, no less than the pupil, discovers that he has a hopeless task in hand; so that he soon comes to content himself with his fee, in return for which he gives his signature, with-

out insisting on fulfilment of every particular in the contract between them. No mere mortal man, in fact, can go on lecturing, with energy and interest in his subject, to indifference, and empty benches, for five or six months successively. And then there is this to be said, that oral instruction is now much less indispensable than it was in former ages. Since we have printed books, we are, in a great measure, independent, nay we are altogether independent, of oral instruction. When Erasmus lectured at Rotterdam (says Mr. Carlyle), if he ever lectured there, or Petrarch at Avignon, as it is said he did, whoever would get from Erasmus or Petrarch what Erasmus or Petrarch had to give, must go to Rotterdam or to Avignon for it. Matters are altogether different in the present day: were Erasmus or Petrarch teaching now at Rotterdam or Avignon, we should have his lecture in London and Paris, in Berlin and New York, in Bombay and on the slopes of the snowy mountains, *in due course of post*, imprinted, indelibly fixed, fitted for reiterated perusal, and even as well calculated to impress sense through the eye, as it would have been had it entered the soul through the porches of the ear. There is no longer any necessity to go to Rotterdam or to Avignon, to hear Erasmus or Petrarch; we carry either or both of them about with us in our pocket wherever we go; we consult them as familiar friends, again and again, and they are never weary with our questions. The school of every gifted man has become the world; his voice reaches to, his soul touches, the men at the antipodes.

Seriously, it seems to us that the system of teaching by lectures ought to undergo revision. Courses might be made much shorter than they are with advantage, and the business of the teacher restricted to giving the *general principles* of his subject, referring to his own, or to another good manual, for all par-

ticulars, demonstrations of which would follow in the laboratory, the wards of the hospital, or the dissecting-room, as the case might require. In this way, it strikes us, the study of the medical sciences could be made as attractive and useful to the student, and pleasant to the professor, as the present system is irksome to both, and, through apathy, unprofitable to him who is peculiarly interested in having it otherwise.

Students complain that they are *over-lectured* at present. And so, indeed, they are, if the brief interval of time into which they crowd attendance, (*qy.* non-attendance,) on all the Courses required of them be considered. The points that meet the body, which, seated in a comfortable apartment, at a table nicely covered with green cloth, set out with wax lights and all the means and appliances for elegant deliberation, is engaged in fixing the curriculum of the medical student, are few and far between in comparison of those which the student himself has to encounter. Let us take the second winter session of the student's life by way of example. In the course of study ordered by the Court of Examiners of Apothecaries' Company for that session, we find—1st, Anatomy and Physiology; 2d, Anatomical Demonstrations; 3d, Dissections; 4th, Principles and Practice of Medicine. This looks feasible on paper, and as if there were no hardship in it; but when we come to consider that, in our best schools, the anatomy and physiology are divided, and properly divided, if the student is to depend on his lectures as means of instruction; and then, that if Practice of Medicine suffices the Apothecaries, the College of Surgeons require Practice of Surgery, upon which attendance must therefore be given; farther, that during his second winter session the student is, or ought to be, paying particular attention to the medical and surgical practice of the hospital; still

farther, that during this session the student very commonly takes out his midwifery ticket; still farther, as it is universally allowed that neither chemistry nor materia medica can be mastered in one semestral attendance, so a second course upon these branches is always signed for by the several teachers during this second winter session; finally, that, Apothecaries' Company *recommend* a course of morbid anatomy, and attendance on the clinical lectures (the most important lectures of all!), which are delivered at the hospital to which the pupil has entered, we see that the student has, in verity, his hands full of work. Enumerating all these Courses in succession, let us see how the reckoning stands in reference to the devoted student in the course of his second winter session:—1st, Descriptive Anatomy; 2d, Physiology and General Anatomy; 3d, Demonstrations; 4th, Dissection by himself; 5th, Chemistry, second course; 6th, Materia Medica, second course; 7th, Principles and Practice of Medicine; 8th, Principles and Practice of Surgery; 9th, Principles and Practice of Midwifery; 10th, Morbid Anatomy; 11th, Hospital Medical Practice; 12th, Hospital Surgical Practice; 13th, Clinical Medical Lectures, occasionally; 14th, Clinical Surgical Lectures, occasionally! Let the luckless wight betake himself to his bed, and die upon this—human nature cannot stand it! Nor is the above reckoning complete, long as it is; he who is working for a degree from the London University will find that he has probably a couple of courses more to follow. He will find himself with General Pathology, or General Therapeutics, or some such other hard dry nut to crack, in addition. And if we are here reminded that the lectures are not given, the hospital visits are not made, every day, this is but another reason with us for find-

ing fault with the system. They ought to be so; it should be imperative on every lecturer to deliver his course on at least five, and it were better that it was six, consecutive days in every week till it was completed. Monday, Wednesday and Friday, or Tuesday, Thursday and Saturday, or Monday, Wednesday, Thursday and Saturday, or any other conjunction or jumble of days—each and all are alike objectionable, all alike destructive of those habits of consecutive attention and regularity that are absolutely indispensable to progress in any undertaking.

And now feeling ourselves fast in this slough of despond into which we have been tumbled by the separate and irrelative enactments of our Colleges of Physicians, Colleges of Surgeons, Companies of Apothecaries, and London Universities, we beg Sir James Graham very earnestly to look down upon us in our sad plight, and entreat him farther, that, taking into his counsels wise and liberally educated men, he come to our rescue forthwith, and by uniformity of educational plan, and reasonable time dedicated to carrying it out, he do something to secure to the community a supply of medical men, not only competent to treat disease in individual instances, but capable of advising with him upon the causes of disease in general, and of suggesting means adequate to their abatement or removal, which, after all, and particularly to the statesman, is the consideration that ought to be paramount.

ROYAL COLLEGE OF SURGEONS.

WE have been requested to give insertion to the following

Statement relating to the New Charter of the Royal College of Surgeons of England.

The Council of the Royal College of Surgeons of England feel that the time is arrived when it is proper for them to offer

some observations, in explanation of the principal changes which the Charter, lately granted by Her Majesty, has occasioned in the constitution of the College, and on the ultimate effect which these changes may be expected to produce in the condition of the Surgical profession. They avail themselves of the opportunity thus afforded to state the principles on which they have hitherto acted, and those on which they propose to act hereafter in the exercise of the new duties which this Charter has imposed upon them.

The Bye-laws which may hereafter be made for the government of the College will not be valid until approved of by the Crown.

The Members of the Council will be elected, not for life, but for a limited term of years.

When vacancies occur in the Council, they will be supplied, not by the Council, but by a new body of Fellows, who will elect the new Members from among themselves.

Fellows of the College, who are not Members of the Council, will be equally eligible to the Court of Examiners with those who are; and future Examiners will hold their office only during the pleasure of the Council.

One object of Her Majesty's Advisers, in establishing the Class of Fellows, was to create a sufficient Constituency for the election of the Council. The same end might have been attained by simpler means, such as giving the franchise to members of a certain standing in the College; but another and expressly avowed purpose was to promote a spirit of emulation among Surgeons, to afford additional inducements to exertion in the cultivation of science, and thus to increase the utility and elevate the character of the Surgical profession. After the expiration of one year from the date of the Charter, no one will be admitted into the rank of Fellows, until he has undergone a strict and lengthened examination, not only in practical surgery, but also in the collateral sciences. They who aspire to become Fellows, without having been previously Members of the College, will be required to have gone through an extended course of professional study in Hospitals and Schools, and to be at least twenty-five years of age. But the Fellowship will not be limited to Candidates of this description; and they who, not having had the same advantage of education, have been admitted as Members at twenty-one years of age, may, after having been engaged in Practice for a certain number of years, represent to the Council that they have continued to study their profession as a science, and claim on these grounds to be examined for the Fellowship. Thus any individual, however

limited his means of improvement may have been in early life, may raise himself by his own industry and talents to the same rank in the College with those who were in the first instance more fortunately situated. No one who desires to attain the Fellowship can complain that it is not within his reach, or that he is prevented from becoming an Elector, or a Member of the Council, or of the Court of Examiners.

Candidates for the Fellowship at twenty-five years of age will have had the opportunity of obtaining a liberal general education, previously to entering on the studies peculiar to their profession; and it is reasonable to expect that the example of such well-educated persons will influence those whose preliminary education has been imperfect, to supply the deficiency by devoting to the acquirement of various knowledge and the general cultivation of the mind, a portion of the leisure which falls to the lot of every young practitioner.

The course to be pursued in the future admission of Fellows is sufficiently obvious; but the new Charter imposed upon the Council another task of much greater difficulty, that of selecting, from among the many thousand Members of the College, a limited number of individuals to be nominated as Fellows in the first instance, so as to form an immediate Constituency for the future election of Members of the Council.

The following provisions of the Charter, on this subject, give to the Council the absolute power of nomination, without conferring on any description of Members the right to be so nominated.

"The Council of the said College, with all convenient speed after the date of these Our Letters Patent, and before the expiration of three calendar months from the date hereof, "and in such manner as the said Council shall deem best, shall elect to be Fellows of the said College any such number of persons, being Members of the said College, and not being in the whole less than 250 nor more than 300, as the said Council shall think proper."

"It shall also be lawful for the Council of the said College, at any time or times, after the expiration of the said three calendar months, and before the expiration of one year from the date thereof, by diploma or diplomas under the seal of the said College, and in such form as the said Council shall think fit, and without any fee, to appoint any other person or persons, being a Member or Members of the said College, to be a Fellow or Fellows of the said Royal College of Surgeons of England."

When these passages of the Charter are considered in reference to each other, and in combination with the circumstance that the

nominations of Fellows by the Council is only a temporary expedient, designed to provide, in the first instance, that Constituency which will be supplied hereafter by Fellows admitted on examination, it will be obvious that the framers of the Charter did not intend that the Fellows to be thus nominated should greatly exceed the number of three hundred.

The Council entered on the duty assigned to them by these provisions of the Charter with a full sense of its invidious nature. They were aware that of those not included in the list of Fellows, a considerable number would feel and express dissatisfaction. But they have done what was required of them to the best of their ability, and have made the selection altogether on public grounds, without favour or prejudice, and uninfluenced by private motives. The following statement will sufficiently explain the principles on which they have acted.

The great majority of the Members of this College are less engaged in the practice of Surgery than in that of Medicine, Midwifery, and Pharmacy, and many of them have arrived at well-deserved eminence in these latter departments of the Medical profession. But the Council, keeping in view the objects for which the College was especially established, have felt it their duty, in the nomination of Fellows, to regard chiefly the qualifications of Members as practitioners in Surgery, or as improvers of those sciences which tend to its advancement.

1. In accordance with this principle, they placed in the list of Fellows the Surgeons of all the Hospitals in England and Wales which are recognised by them as Schools of Surgery; and they did so under the conviction that the Surgeons of large hospitals have the best opportunity of experience in Surgery, and that they are the persons principally consulted, in private practice, and referred to by other practitioners, in surgical cases.

2. But they were aware that in several parts of the kingdom there are Members of the College having considerable reputation as Surgeons, and called into consultation in surgical cases by the practitioners in their neighbourhood, although they have no connexion with Hospitals; and the Council thought it right to place the most eminent of such persons on the list of Fellows. In executing this part of their duties great circumspection was required, lest improper names should be inserted and proper ones omitted. In this respect the list is incomplete, there being individuals of this class whose claims are still under consideration.

3. Not being well acquainted with the qualifications of Military and Naval Surgeons, and being at the same time desirous

of doing justice to them, the Council applied for assistance to the heads of their respective departments; and many of the names included in the schedule of Fellows are the result of this application.

4. There are in London several practitioners in Surgery, who, though not connected with Hospitals, were considered eligible to the Council under the former Charter and according to former usages, and the Council therefore thought that they ought to be admitted to the Fellowship. Many of these gentlemen are well known and much esteemed by the profession; and the question was, not whether they should be elevated to a new position, but whether they should be displaced from one which they had previously occupied.

5. Some individuals have been placed on the list of Fellows from having distinguished themselves in cultivating the kindred sciences of Anatomy, Physiology, and Natural History. The Council cannot but regard such persons as ornaments of the College, and it will be gratifying to them to find others of the same class who may be added to the list.

6. Other names have been inserted for special reasons, being principally those of Teachers who had been recognised by former acts of the Council, or of persons holding important public offices. Among the latter are four Senators of the University of London.

The Council are empowered to nominate an additional number of Fellows before the expiration of the first year from the date of the Charter. This will enable them to supply the deficiencies of the former list, in anticipation of which it is evident that this clause was introduced. In the future nomination of Fellows, the Council see no reason why they should depart from the general principles on which they have hitherto acted; though they will make it their object to omit the name of no individual who is held in esteem by the other Members of the College for his surgical experience and scientific attainments. For those who are not yet so distinguished, there is an honourable method of obtaining the Fellowship by examination.

In conclusion, the Council take the liberty of observing, that no alteration in the Charter, nor any legislative enactment, can materially change the condition of those who have been for some time established in practice. In the medical profession each individual makes his own place in society; intellect, knowledge, and integrity, being equally appreciated and respected in every grade and station. If the changes introduced by the present Charter are to have the effect of elevating the character of the surgical profession generally, it will be in the next rather

than in the present generation; and if the elder class of practitioners are interested in these changes, it is no less on their own account, than on that of their sons and successors.

By order of the Council,
EDMUND BELFOUR, Sec.

Lincoln's Inn Fields,
May 25, 1844.

REPORTS OF CASES
OCCURRING AT
THE WESTMINSTER HOSPITAL:
WITH REMARKS,
By B. PHILLIPS, Esq. F.R.S.

Lacerated wound of Leg; Erysipelatous Inflammation; Gangrene; Death.

A. B. *et.* 43, a brewer's drayman, was admitted into Northumberland Ward, at 3 A. M. of the 17th of March.

He had fallen from his dray while riding; the wheel had passed over the right leg, and caused a lacerated wound of between five and six inches in length, exposing the internal surface of the tibia: there was considerable hæmorrhage from the wound at the time of his admission, but it soon ceased. The edges of the wound were brought together by sutures and adhesive straps, and a roller was applied from the foot to the knee. When seen by Mr. Phillips, at 1 o'clock P. M., he had not slept, but did not complain much of the injured limb: ordered an aperient draught, and the sutures to be removed if there was any tension. In the evening he complained of the leg being very painful, and of its throbbing very much; and upon removing the bandage and plasters the outer side of the limb was found in a state of erysipelatous inflammation: the sutures were removed, and the limb was enveloped in warm fomentations. Early in the morning of the 18th there was a sudden declension of the vital powers, and at 10 A. M. the whole of the integuments of the leg were in a gangrenous state, which was rapidly spreading up the thigh: so rapid was its progress, that in a few hours it had extended to the abdomen. Brandy and ammonia were given to him, and various local applications were used to endeavour to check its progress, but without effect, and he died about eight in the evening.

Remarks.—The great interest in this case is to be found in the circumstance that, in a man of middle age, a wound of no very serious magnitude ended in gangrene within 24 hours of the receipt of the injury. Hospital surgeons are familiar with the fact that wounds are apt to become erysipelatous or

gangrenous, and that depletion is very ill borne by those persons who are employed by brewers, and especially those who are in the capacity of draymen: the work they do is exceedingly laborious, and to help them to meet the great calls upon their strength, their employers are accustomed to allow them large quantities of beer. In the present case it was ascertained that the man was accustomed to drink from 12 to 16 pints daily. So much stimulus brings about a condition verging upon constitutional irritation, and a slight cause will sometimes turn the scale; rarely, however, do the powers of life flag so suddenly as in this case.—About 3 o'clock one morning, the injury, and that not a very severe one, is sustained: no depletory means were employed, and at 9 o'clock the next day an almost pulseless state of collapse comes on, from which no stimulus, either by extensive counter-irritation, or other means, roused him at all, and he died in the evening of that day. There was no disease of the vascular system even in the thigh of the affected side. The lesson which may be learnt from this case is, that in such patients it is unsafe to discontinue the use of the accustomed stimulus even for 24 hours. It is possible that three or four pints of beer, taken on the day of the injury, might have altered the result.

Mammary Abscess in the fifth month of Pregnancy: Treatment: Cure.

Eliza M.—, *et.* 20, unmarried, a domestic servant, admitted March 19th, states that about a fortnight previous to admission she first began to feel pain in the right breast, and on examining it she found a hard swelling, about the size of a walnut, which rapidly increased until the breast became more than double its natural size; and on the Saturday previous to her admission it broke in several places, and a thick yellowish matter was discharged, but with little diminution in the size of the breast. On her admission, the breast had all the appearances of a large scrofulous abscess, with numerous ulcerations on its surface, from which a great quantity of pus escaped: on pressure by the finger in some parts a sensation similar to that of a piece of wet sponge is communicated, in others the gland is hard and lobulated. Her general health is a good deal affected; she has sleepless nights, no appetite, pulse small and weak, countenance pale and anxious. Upon questioning her, she admitted that she is between five and six months advanced in pregnancy, and that her health had previously been good: she has not suffered at all from the usual concomitants of that state, and she never received a blow upon, or in any way injured the breast, that she is aware of.

Ordered to remain in bed, and apply a poultice over the entire surface of the breast, to take $\frac{3j.$ Mist. Ferri Comp. ter die, and to have full diet and a pint of porter daily.

21st.—Complains of great pain at the lower part of the breast, which keeps her awake.

To have an anodyne at bed-time.

Continued in much the same state till the 25th, when Mr. Phillips made an incision into the most depending part of the breast, which gave exit to a large quantity of healthy-looking pus, and afforded her great relief.

30th.—The breast is now nearly a third less, and discharges freely. Health considerably improved. The discharge gradually lessened in quantity, and the breast in size, and on the 14th April Mr. Phillips directed that pressure should be applied to it by means of soap strapping and a bandage, by which means the breast is now reduced nearly to its natural size; but there is considerable hardness remaining: the patient's health is in a great measure restored, and in a short time she will leave the hospital.

REMARKS.—This case is curious in the circumstance that an abscess bearing all the ordinary marks of breast-abscess after delivery, was developed in the fifth month of pregnancy, in the absence of any other apparent cause of irritation to the organ than the state of the uterus. The appearance of the woman was that of one who had recently gone through the suffering of parturition; the affected breast had large tortuous veins ramifying over its surface; the areola around the nipple was very dark, and it was stated by the house-surgeon that a secretion could be expressed from the nipple of the sound side. The same means of treatment which would have been employed in abscess after childbirth were employed here, and with complete success. The breast was very large after the escape of all the pus contained in its tissue, but it yielded to pressure made over it by means of soap strapping and bandaging, and the organ is now reduced to as nearly as may be its natural size. In cases of breast-abscess after delivery, which are frequently seen at the St. Mary-lo-bone Infirmary, I have had abundant opportunities of satisfying myself that, after free evacuation of the different purulent collections, the only way to prevent the extension of the disease through the lax tissue of the part is the prudent employment of pressure. It is best made by soap strapping, carried a good way around the chest, so as to get a firm hold, and then equally supported by a roller. It is of course necessary to leave uncovered by the strapping any sinus that may be present.

of doing justice to them, the Council applied for assistance to the heads of their respective departments; and many of the names included in the schedule of Fellows are the result of this application.

4. There are in London several practitioners in Surgery, who, though not connected with Hospitals, were considered eligible to the Council under the former Charter and according to former usages, and the Council therefore thought that they ought to be admitted to the Fellowship. Many of these gentlemen are well known and much esteemed by the profession; and the question was, not whether they should be elevated to a new position, but whether they should be displaced from one which they had previously occupied.

5. Some individuals have been placed on the list of Fellows from having distinguished themselves in cultivating the kindred sciences of Anatomy, Physiology, and Natural History. The Council cannot but regard such persons as ornaments of the College, and it will be gratifying to them to find others of the same class who may be added to the list.

6. Other names have been inserted for special reasons, being principally those of Teachers who had been recognised by former acts of the Council, or of persons holding important public offices. Among the latter are four Senators of the University of London.

The Council are empowered to nominate an additional number of Fellows before the expiration of the first year from the date of the Charter. This will enable them to supply the deficiencies of the former list, in anticipation of which it is evident that this clause was introduced. In the future nomination of Fellows, the Council see no reason why they should depart from the general principles on which they have hitherto acted; though they will make it their object to omit the name of no individual who is held in esteem by the other Members of the College for his surgical experience and scientific attainments. For those who are not yet so distinguished, there is an honourable method of obtaining the Fellowship by examination.

In conclusion, the Council take the liberty of observing, that no alteration in the Charter, nor any legislative enactment, can materially change the condition of those who have been for some time established in practice. In the medical profession each individual makes his own place in society; intellect, knowledge, and integrity, being equally appreciated and respected in every grade and station. If the changes introduced by the present Charter are to have the effect of elevating the character of the surgical profession generally, it will be in the next rather

Abcess of the Septum Narium simulating Polypus; Evacuation of the matter; Cure.

John Brown, æt. 26, presented himself among the out-patients, on March 20th. He states that, about two months back, he first found a difficulty in breathing through the nose, and perceived a small swelling in the left nostril; it gradually increased in size until it became so inconvenient that he was forced to apply for relief. There is now a tumor nearly filling the cavity of the left nostril; there is also a fulness over the septum on the opposite side; it has all the appearances of an ordinary vascular polypus, excepting its broader base.

Ordered to apply a lotion containing Sulph. Zinci to it frequently.

24th.—It appears slightly shrank.

30th.—Much the same.

To have two leeches applied to the part, and to continue the lotion.

April 6th.—Mr. Phillips being doubtful of the nature of the tumor, introduced a grooved needle into it, and ascertained that its contents were pus: he then put a lancet into it, and between three and four drachms of pus escaped.

13th.—The opening having closed, it was again opened, and a similar quantity of pus let out. He came again on the 18th, when there was little appearance of the swelling remaining.

May 7th.—He is now quite well.

REMARKS.—This case illustrates a form of disease by no means of frequent occurrence—abscess of the septum of the nose. The patient was a healthy-looking young man; he had had a blow on the nose some time before, which may have been the source of irritation. The tumor had all the appearance of an ordinary vascular polypus, save that its base was larger than is usual in such cases. The fact of a thickening being present on the other side of the septum induced me to suspect that the tumor was possibly abscess, and to assure myself of this, before attempting to do more, I passed the grooved needle into it.

I have twice before observed abscess of the septum. In one case the tumor was grasped by the forceps, and torn off, but it left the surface of the septum exposed; which afterwards became carious, and ultimately was perforated, and the opening did not close while I had an opportunity of observing the case.

THE HOTEL-DIEU 50 YEARS AGO.

In 1786, diseases and infirmities of every nature and description were treated in the

Hôtel-Dieu. The patient who arrived was placed in the bed and sheets of the patient who had just died, affected with the small-pox, it might be, or some other disease, complicated with itch. Two insane patients were always laid in one bed. (Think of two madmen under the same coverlid!) In the ward exclusively reserved for small-pox patients, there were often six adults, or eight children, laid in a bed less than 5 feet in width. On the female side there was no separate ward for small-pox; the patient labouring under a trifling fever had perchance for her bed-fellow a woman in the height of this dreadful malady! The patients were laid head and heels, the feet of one being in contact with the shoulders of another; and as four, and even six, were laid in a bed 4 ft. 8 in. English in width, each could have had no more than from nine to ten inches for his portion. But as a man of ordinary stature is eighteen or nineteen inches across the shoulders, it was, of course, impossible for the unfortunate people to be all in bed together, unless laid upon their sides and completely motionless. No one could move, or attempt to turn, without disturbing or waking those on either side of him; it was therefore usual for them to have the bed by turns, two or three sitting up, as long as they were able to do so, two or three lying down. And then the food and the physic destined for one was frequently given to another; the dying were frequently heard to curse the kindest hand that sought to soothe them; life in such wretchedness being less desirable or desired than death. Dreadful to relate, dreadful to think of, those who died in the night always remained mingled with the living till morning! By and by an *improvement*—the first that was made in the Hôtel-Dieu—was introduced: the testers were fitted up as beds, and the patients were placed in tiers one over the other! The heart sickens, the understanding shrinks from, the spirit is confounded, with the contemplation of so much misery; and yet this hospital existed fifty years ago, in the midst of a capital, the centre of the arts, of learning, of polished manners, beside the palace of an opulent archbishop, at the door of a magnificent cathedral! It was in such circumstances that the wretched sufferer from disease, under the deceitful mask of charity, was tempted to his destruction; for the diseases were of twice the duration at the Hôtel-Dieu that they were at La Charité, and the mortality was twice as great; all who were trepanned died, and the women in childbed fell victims in a frightful proportion.

At whose door lies the charge of this barbarous organization? At that of the medical staff? No, no; far otherwise. By an

inconceivable anomaly the medical officers of hospitals have never had more than a very secondary influence over their administration. No, but at that of the vulgar omnipotence of routine and of ignorance. "The Hôtel-Dieu," said the sage Bailly, "has perhaps existed since the seventh century; and if this hospital be the worst of all, it is only so because it is the oldest. There has still been a leaning to keep things as they were in the beginning; constancy in every thing has appeared a duty; hence the difficulty that aught new, however useful, finds in gaining an entrance. All reform was extremely difficult; the administration that must be convinced was numerous; it was an enormous mass to move." But this magnitude of the mass, the difficulties of the enterprise, did not daunt the members of the Academy of Sciences, with Bailly, Laplace, and Lavoisier, at their head. Every patient is now laid in his own bed; and that he is so is mainly due to the persevering unanimity, the courageous efforts, of the Academy of Sciences. The poor man ought to be aware of this; he will assuredly not forget it. Happy, my friends, happy the Academy that can crown itself with such dear recollections.—*M. Arago, in his Eloge de Bailly.*

[How sad to think that two of these noble natures fell victims to the fearful madness of the French Revolution!—Bailly and Lavoisier are said to have been carried to the slaughter in the same cart!—*Ed.*]

CASE OF TWINS,

IN WHICH BOTH PLACENTÆ WERE EXPULSED PREVIOUS TO THE DELIVERY OF THE LAST FŒTUS, WITHOUT CONSEQUENT HÆMORRHAGE.

By SAMUEL TYLER, M.D. of Frederick, Md. My father was requested to attend a female in labour in the morning of the 6th July, 1843, 10 o'clock A.M. She had been delivered by her mistress two hours before (8 o'clock A.M.) of a fine child. In a reasonable time after the expulsion of the fœtus, the placenta was discharged. The mistress observed that the placenta presented an unusual appearance, and that the cord seemed larger than natural, but it was not until she had divided the funis that she discovered there was another fœtus "in utero," and that she had mistaken a double placenta and a double cord for an enlarged condition of those two important organs.

When my father arrived, he made an examination per vaginam, and discovered that the remaining fœtus presented the left shoulder. It was then more than an hour since the cord had been severed, and of course the life of the fœtus destroyed. In addition to the unfavourable circumstance of a shoulder presentation, there was firm

hour-glass contraction of the uterine fibres around the body of the child. Having, in conjunction with the means usually calculated to relieve so firm a contraction of muscular fibre, made many unsuccessful efforts to turn the fœtus in order to convert it into a footling or breech case, he sent for me. On my arrival, I soon discovered (indeed it was for that purpose he sent for me) that embryotomy offered the only chance of relief to the female. After making several equally ineffectual efforts at turning, I proceeded to perform the operation, which consisted in removing with the scalpel the left arm, at the shoulder-joint, and then opening the thorax by a puncture or incision between two of the ribs, and thus partially evacuating its contents. The delivery was effected, after compressing the thorax and abdomen, by carrying up the right hand to the breech, passing the finger into the rectum, bringing down the breech, and then finishing the delivery "*secundum artem.*"

The patient was placed in a comfortable position, and every precaution taken to prevent, or rather to relieve, what seemed inevitable, viz: copious hæmorrhage; but none occurred; on the contrary, she went on favourably, soon entirely recovered, and is now nursing her infant.

Here therefore is a case not merely of simple placenta prævia, but a double surface exposed, there having been two placentæ; the fibres of the womb, first in a state of rigid contraction, then the irritation consequent upon the performance of embryotomy, and lastly a state of excessive relaxation, and still no hæmorrhage.—*American Journal of the Medical Sciences.*

DIVISION OF THE PORTIO-DURA; EXCESSIVE PAIN.

THE following brief narration is interesting in a physiological point of view. A dancing-master had a tumor developed over the articular surface of the lower jaw, to remove which means of every kind were tried in vain: the tumor at length having acquired the size of half an apple, the patient consented to have it removed by operation, in the course of which, the surgeon saw that the trunk of the facial nerve passed right through the middle of the morbid mass, a mixture of steatoma and hydatids. Seeing no means of sparing it, the surgeon cut it through at one lusty stroke of the knife. The pain occasioned by this seemed horrible. The patient threw off the three assistants who were holding him, sprung from the seat, looked wildly around, and stretched out his hands in agony. The spectacle was made the more piteous by the semiparalysis of the face and distortion of the features that instantly ensued: the mouth was drawn

completely over to the other side, the angle on the paralysed side hung down relaxed, the cheek lay hollow and meaningless; the eye seemed sunken and smaller. It was by and by found that three-fourths of an inch of the trunk of the facial had been removed.

What is still farther remarkable is this: that the deformity did not continue even in the evening of the same day; the features had recovered themselves greatly, and after a fortnight, unless when the patient spoke, particular attention would have been required to perceive that anything was amiss with him.—*Bredow, in Caspar's Wochenschrift*, No. 12, 1844.

THE APOTHECARIES OF BRUGES.

IN the year 1683, in consequence of a complaint preferred by the Apothecaries of Bruges, the medical practitioners were forbidden to dispense their own medicines under a heavy penalty. Only during the first three days of the annual fair were charlatans and tooth-drawers tolerated in that town.—*De Meyer, Origine des Apothicaires de Bruges*, Bruges 1842.

CASE OF

ABSCESS OF THE TONGUE.

By DR. MOLLER.

A LOCKSMITH applied for advice regarding a swelling under the chin, with violent pain at the root of the tongue, almost wholly preventing deglutition. Upon examination a large tumor was found in the tongue, that nearly filled the entire cavity of the mouth: it was dark coloured, and fluctuating. There was no time to lose. A bistoury armed with linen to near its point was plunged into the swelling, whereby a great quantity of thin pus was evacuated, and the patient straightway relieved. The wound healed in eight days. The tumor under the chin was treated in the same way. The patient was sixty years old, and of phthisical habit—a circumstance in accordance with what certain writers have advanced, namely, that phthisical individuals are more especially prone to this rare kind of abscess.—*Oppenheim's Zeitschrift*, Feb. 1844, p. 252.

THERAPEUTICAL POWERS OF IODIDE OF POTASSIUM.

IN a communication to the *Provincial Medical Journal*, April 24th, Dr. Oke gives the results of an extended therapeutical experience of the iodide of potassium. He had not found it of any service in cases of abdominal tumor, scirrhus induration, or ulcerated cancer, lupus, indurated glands, scrofulous ulceration, affections of the lungs, enlargement of the liver, ascites, or encysted dropsy. The diseases in which he had found

the medicine useful, on the contrary, were phagedenic ulceration, disease of the pericæteum, and chronic rheumatism.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

Gentlemen admitted Members, May 24.—H. Kingsley.—N. J. Dampier.—T. Callaway.—S. J. Remnant.—R. Ellis.—E. S. Protheroe.—R. H. Donovan.—J. M. Moulton.—J. Cowburn.—T. Hipwell.—W. C. Byass.—G. F. Wills.—H. Fearnside.

THE LONDON MEDICAL GAZETTE,

BEING A
WEEKLY JOURNAL

OF

Medicine and the Collateral Sciences.

FRIDAY, JUNE 7, 1844.

ON THE CAUSES OF OCCASIONAL FAILURE IN DETECTING CALCULI IN THE BLADDER.

By WILLIAM COULSON,
Surgeon to the Magdalen Hospital, &c.
(For the Medical Gazette.)

SURGEONS who have had much experience in the treatment of calculous affections must have often felt considerable difficulty in determining on the presence of stone in the bladder. Numerous instances are on record of large stones being found after death, the existence of which, though strongly suspected, could never be verified during life by the most careful examination. A short time ago I saw a gentleman who had been sounded by an experienced surgeon, who was unable to say whether there was a stone in the bladder or not; the examination caused a good deal of pain, and was never repeated. The patient died in sixteen months from the period of being sounded, and a stone was found in the bladder weighing four ounces and a half—too large, it is but natural to think, to have formed since the sounding: the bladder was rather small, and the prostate not enlarged. I have been informed that the largest calculus in the museum of St. Bartholomew's Hospital was taken from a patient who was often sounded, but in whom the presence of stone could never be ascertained during life, although there was little or no doubt in the mind of the surgeon of its existence. In the museum of the Royal College of Surgeons there is a bladder taken from a man who committed suicide after long and unalleviated suffering from stone, the presence of which had never been detected, though he was repeatedly sounded by the late Mr. Abernethy and others. The bladder contains a large rough calculus of an oval form, and mea-

suring in its several diameter, about $1\frac{1}{2}$, $1\frac{1}{2}$, and 1 inch. The mucous membrane is thickened, indurated, and superficially ulcerated. The muscular and cellular coats also are thickened, and the peritoneum and other tissues around the bladder appear condensed and unnaturally adherent. The ureters are dilated and thickened; both the bladder and prostate are of ordinary size.—(971 a, Bladder 31). "Repeated examinations of the bladder with the catheter," observes M. Civiale*, "have failed, even in the hands of the most experienced surgeons, such as Cheselden, Pelletan, and Dupuytren, to determine the existence of stone. Verzaschat, Benevoli†, Duretus‡, Riverius||, Marcellus Donatus¶, Chesneau**, Valentint††, Riolanus‡‡, Morgagni§§, Covillard||||, Tolet¶¶, Colot***, Morand†††, Deschamps‡‡‡, and Chopart§§§, state facts which prove that large calculi, of the size even of a hen's or duck's egg, nearly filling the bladder, have escaped the most minute and careful examination. Even where there are numerous calculi they cannot always be detected. Colot is said to have sounded a man of

sixty, and though unable to ascertain the existence of stone, operated on him, and extracted twenty-two calculi, which were hard, and of the size of a hazel-nut. Lapeyronie died of stone; his bladder contained a calculus weighing more than three ounces, which was not discovered during life, although he had been sounded several times. Portal and Distel also died of this affection, but in neither could the stone be detected with the sound until it was too late to operate. M. Kruger Hansen* relates the case of a man who suffered for a long time from dysuria, and in whom a stone could never be felt. After death a very large calculus, covered with small pointed elevations, was found in the bladder." M. Leroy† also mentions similar instances.

Cases not unfrequently occur in which a stone is felt distinctly at one time, but cannot be felt at another, although the examination is made by the same surgeon, and, as nearly as possible, under the same circumstances.‡

A boy, aged 12 years, was admitted into one of the metropolitan hospitals with symptoms of stone: on the first examination, a stone was felt, but when the boy was put on the table to be operated upon, the stone could not be detected. He was brought a second time for the same purpose, but no stone could be felt. The parents shortly after removed him from the hospital. Not long after, the boy was brought to the General Dispensary, and the circumstances of the case related by the parent. It was determined to prepare the boy as for the operation for stone, and then sound him, so that in the event of a calculus being felt the operation might at once be performed. Accompanied by Mr. Jeremiah Pereira, and some other friends, I went to the patient's residence. On introducing a sound, the calculus was distinctly felt; the operation was at once performed; and a calculus, weighing a little more than a drachm, removed. Last year two cases occurred to me in which considerable difficulty was felt by myself and others in detecting a stone in the bladder. One, a child three years old, had been taken to an hospital and examined three times, but no stone was detected. I saw the child afterwards and sounded it three times, allowing an interval of a month between each examination, and it was only on the third occasion that I detected the calculus. Just before operating, considerable difficulty

was again experienced in feeling the stone; and it was not until the finger was introduced into the rectum, and the neck of the bladder raised, that the stone could be felt. The operation was then performed, and a stone composed of lithate of ammonia, and weighing one drachm and six grains, was removed. It was situated in a pouch at the neck of the bladder, so that the finger, on entering the bladder, passed over the calculus towards the fundus. I have no doubt that if the finger had been introduced into the rectum when the child had been previously sounded, the stone would have been felt.

The other case was a boy five years old, in whom I distinctly felt a stone on the first examination; but on repeating it a month afterwards I was unable to detect the calculus. The child was sounded by one of the most experienced lithotomists in the metropolis; but, after a careful examination, he could not detect a stone. After waiting three months, I sounded the child again; and at the extremity of the sound, towards the fundus of the bladder, I felt the stone. The operation was then performed, and a mulberry calculus, weighing one drachm and forty-three grains, was removed. The operation revealed the cause of the difficulty: the bladder was very capacious for a child of his age, and the stone was situated at its fundus. I could not touch the stone, as in ordinary cases, with my finger, nor seize it with the forceps, until pressure had been made over the bladder, and the child's body raised. In these two cases I had the able assistance of Mr. Quain.

The following interesting case, of a boy sixteen years of age, who had suffered a long time from stone, is related by Sir Benjamin Brodie*, and bears strongly on my present subject. "There were these remarkable circumstances in his case, viz. that the stone could sometimes be felt distinctly with the sound, appearing to be of a large size, while at other times it could not be felt at all; and that sometimes, when the bladder was empty of urine, it could be perceived distinctly with the finger from the rectum, while at other times, when there was urine in the bladder, it could not be detected at all by this mode of examination. In performing the operation, when I had introduced my finger into the bladder, I could at first discern no stone; at last I felt it on the anterior part of the bladder, behind the pubes. It was not lying loose in the cavity of the bladder, but evidently contained in a cyst, communicating with the bladder by a round opening. By means of a probe-pointed bistoury, I carefully dilated the orifice of the cyst, and then, introducing my finger, sepa-

‡ Fig. 9, Plate I., in Mr. Cross's work on Urinary Calculus, "refers to two calculi found after death in a gentleman who was about to submit to lithotomy; but the stone, previously ascertained to be in the bladder, could not then be felt."

* Lectures on the Diseases of the Urinary Organs, 3d edition, p. 322.

rated the membrane of it from the calculus until I was enabled to take hold of the stone with the forceps. The calculus is preserved among those in our museum. It was not only encysted, but adhering also; for it was brought away with a portion of the membranous lining of the cyst closely attached to it. The boy recovered."

Cysts or pouches are sometimes formed by the protrusion of the mucous membrane between the muscular fibres of the bladder, into which calculi, that had been loose in the bladder, and could be easily recognized with a sound, find their way, and cannot afterwards be felt; or it may happen, that when such a pouch exists, the calculus may sometimes be contained in it, and at other times make its escape into the bladder, a peculiarity which will readily account for a calculus being sometimes easily felt, and at other times not felt at all. The distinguished surgeon from whom I have just quoted* relates the following case illustrative of this condition of the bladder. "The case is, in many respects, remarkable. I discovered a stone in a gentleman's bladder; but he was advanced in years; and as, for the most part, he suffered very little inconvenience from the disease, he did not wish to go through any dangerous operation for the sake of obtaining relief; nor did I think it right, considering all the circumstances, to urge him to submit to it. He went on, in general suffering little or nothing. He was a convivial man, dining a great deal in society, as if he had no ailment. Every now and then, however, he was suddenly seized with the usual symptoms of stone in the bladder, and very severe ones too: he then sent to me. I kept him in the horizontal posture, prescribed him an opiate clyster, and in the course of a few days, sometimes sooner, sometimes later, the attack subsided; he was again at his ease, and enabled to return to his usual habits. I had been occasionally in attendance on him for three or four years, when he was seized with a severe cold, which ended in a pleurisy, of which he died. On examining the body, I found the stone imbedded in a cyst near the fundus of the bladder. The cyst was formed, in this case, not by the protrusion of the mucous membrane between the muscular fibres, but by a dilatation of both tunics of the bladder, the muscular as well as the mucous. The stone was not so closely embraced by the cyst as to prevent it occasionally slipping out of it; and I suspect that this actually happened, and that it was when the stone lay in the cyst that the patient was free from the usual symptoms of calculus, and that his sufferings took place when the stone escaped from it into the general cavity of the bladder."

* Op. cit. 3d edition, p. 258.

Again, the bladder may ulcerate, and the stone either wholly or partially escape.

The causes of the difficulty in detecting stone in the bladder may be arranged under the following heads:—

1. Enlargement of the prostate.
2. Fungous growths at the neck of the bladder.
3. Other morbid conditions of the bladder, as cysts, fungus, polypus, &c.
4. Certain peculiarities in the situation and size of the stone*.

When there is a fungous growth at the neck of the bladder, it must offer great obstacles to the detection of a calculus, and when a calculus becomes encysted an insurmountable source of difficulty exists. In other cases of difficulty, attention to a few practical rules will much assist us. In examining persons with enlargement of the prostate, who are suspected to labour under stone, a sound of the shape and curve of the lithotrite is certainly better fitted than the sound in common use for reaching the *bas fond* of the bladder, the probable situation of stone in these cases. Mr. Cross†, p. 55, mentions that Mr. Pearson, (more than thirty years ago), occasionally used a catheter of this shape, and found it enter the bladder when an instrument of a different shape would not. No examination of the bladder, when the prostate is enlarged, should be considered complete, in which an instrument of this shape (provided the stone is not felt with the common sound) has not been employed. Again, the introduction of the finger into the rectum, is an auxiliary, which, especially in these cases, and indeed in most other difficult cases of stone, should not be neglected. It is singular that M. Civiale, whose experience in calculous affections is so great, should speak so lightly of this mode of examination‡. In the second case which I have related, the stone could not be felt with the sound, until the finger was introduced into the rectum, and the operation was almost on the point of being

* I purposely exclude such a contracted state of the urethra as prevents any examination at all of the bladder.

† Treatise on the Formation, Constituents, and Extraction of Urinary Calculus. 4to. Lond. 1835.

‡ "En effet, veut-on explorer la partie prostatique de l'urètre et le col vésical? le doigt se trouve séparé de la partie malade par un plancher épais, dur et résistant, à travers lequel le tact le plus délicat ne saurait rien discerner. S'agit-il d'atteindre la pierre située dans le bas-fond de la vessie? pour peu que la prostate soit engorgée, et même alors qu'elle ne l'est pas, le doigt ne saurait arriver jusque là; sa pulpe appuie sur la face inférieure de la prostate, et rarement elle s'étend au bord postérieur, entre les vésicules séminales et les conduits spermatiques; les cas dans lesquels il serait le plus facile de palper cette région de la vessie sont précisément ceux où l'on n'a aucun intérêt d'introduire le doigt dans le rectum."—*Traité d'Affectation Calculuse*, p. 476.

abandoned. Mr. Cross says, "I should deem myself as little justified in omitting this method of exploration, as in operating without having sounded at all."

In children, and in grown up persons with irritable bladders, the contraction of the organ renders it difficult to detect the calculus; it is then embraced by the folds of the bladder, and escapes the touch of the sound. In this state, it is desirable not to examine the bladder in an empty state; and if this organ be irritable, the irritation should be subdued by appropriate means, to enable the bladder to contain a fair quantity of urine. In the first case which I have detailed, I have little doubt in my own mind that the fear of the operation caused the escape of the urine, and that the stone was consequently embraced by the folds of the bladder, and could not be felt. When the operation was performed, the boy had no previous knowledge of what was to take place, for I was in a state of uncertainty myself, from what had occurred, whether I should be able to feel the calculus. In the third case which I have given, the situation of the stone was the cause of the difficulty in detecting it. If a calculus be situated behind the pubes, as in the first case which I have quoted from Sir Benjamin Brodie, or be adherent to the fundus of the bladder, or be impacted in the vesical extremity of the ureter (one portion being within the ureter and the other projecting into the bladder, as occurred in a case of Dr. Prout's) great difficulty will be experienced in detecting the stone. In suspected cases of this kind the patient should be examined in various positions, and the bladder should contain a moderate quantity of fluid. Again, the small size of a stone may be the source of difficulty in detecting it. Sir Benjamin Brodie* says, "I have known the most practised surgeons, with the most delicate sense of touch possible, use the sound several times, where the calculus was of a small size, before they felt it so distinctly as to be satisfied of its existence."

ON THE
DECREASE OF DISEASE THROUGH
THE PROGRESS OF CIVILIZATION.

By C. F. H. MARX, M.D.

Professor of Pathology in the University of
Goettingen.

(For the Medical Gazette.)

[Concluded from p. 301.]

Yellow fever is a disease which has several times invaded the continent of Europe, and upon the contagious or

non-contagious nature of which the most opposite opinions have been entertained and published. The disease, however, is known to be endemical in countries where other forms of remittent and intermittent fever prevail, particularly the West India Islands. In healthy seasons the type of fever is there more simple, the disease is more mild; it presents the characters of simple intermittent or remittent fever, and yellowness of skin scarcely or never occurs; in unhealthy seasons, again, along with very general prevalence of the remittent form in every degree of aggravated severity, the yellow skin is met with frequently, and the disease becomes yellow fever, though it is but the old familiar malady. These bad forms of remittent fever are acknowledged never to extend beyond a certain elevation above the sea-line; this level passed, patients can be attended without the slightest risk of infection; and even the nurses and hospital-sergeants, who live among the patients in the feverish districts, when the disease is at the height, are observed to be but rarely attacked by it; when they are, it is because they have been exposed beyond the bounds of the barrack or hospital to the general causes which engender the disease. It may be said confidently that the most able and, in reference to yellow fever, the most experienced medical officers of the British army, have expressed themselves almost unanimously against the contagiousness of the disease. As to the idea of its having had its source and origin in slave-ships, this is plainly untenable. Fevers of the worst kind, yellow fever in its most aggravated form, may and do occur there; but this is because of the circumstances in which the unhappy wretches are placed on board of slave ships: the atmosphere of the hell in which they are crowded is poison as deadly to the lungs as any the deadliest drug we wot of to the stomach*.

* It is very sad to think of the fact, but there can be no doubt of its being true, that the attempts of the more civilized and humane nations of the earth to put an end to the slave-trade, should have rendered it infinitely more destructive than it used to be, and, to all appearance, scarcely to have abated its activity. The scarcity of the article has caused its price to rise, and held out a temptation to the cupidity of man which seems irresistible. The slave is now built and fitted solely with a view to speed, that they may escape the cruisers, and without the slightest regard to the stowage of the cargo. The effect of this is, that living human beings are packed precisely as

* Op. cit. p. 377. .

Intermittent fever or *ague*, of which it may be said, more truly than of any other disease that it exerts its power in virtue of immemorial possession of the soil, is losing one domain after another. Although it lies not within the empire of wishes to win the marsh and fen for the use of man, by well-directed efforts and perseverance we still greatly contract their extent; we carry off stagnant waters by well-directed drains; turn aside the spring that floods the morass; and even shut out the sea from many a fertile acre seated below the level of its bed. In districts where rice and hemp are grown; it is found that much may be done to lessen the insalubrity of the culture by planting trees, and keeping the ditches well scoured; just as, in reference to towns, attention to the sewerage, to filling up old and stinking ditches, to the supply of pure water, wholesome food, and of airy houses, seems competent to put an end to ague in all its shapes, even in localities where it had established a title to be held indigenous and truly endemical.

The history of the improvement of the soil supplies us with the most striking and interesting examples in illustration of these statements*. The

if they were lifeless mummies, and apparently without the slightest suspicion that they require more than room to sit up or lie down in; the space between the floor upon which they are stretched and the deck above them is not more than two feet and a half, and, as is said, sometimes not more than eighteen inches; and there are no adequate means of ventilation provided. Venetian senators, Spanish inquisitors, North American Indians, never inflicted such tortures upon their enemies or opponents as are thus ruthlessly, but unintentionally, inflicted upon the crowds of naked savages in the slaving-schooners of the present day.—*Esq. Ed.*

* Many of the most agreeable and even healthy parts of England were at a no very remote period barren heaths, and pestiferous marshes. [All the world knows how the fens of Lincolnshire and Cambridgeshire have shrunk before the spirit of improvement; in innumerable districts where ague was once endemical, where young and old laid their account with an attack every spring and fall, the disease has not been seen in the course of the present generation; and in others, where it still lingers, it is less frequent than it was, and less obstinate. Many parts of Essex, and I presume it is the same with other districts, however, still hold great enmity with the constitution of strangers. It is very dangerous, for instance, for the Essex farmer to cross the Thames to seek his bridle among the blooming maidens of Kent; if he does, he is almost certainly a widower within a few years.—*Esq. Ed.*] Greece, reviving from the ashes of her former greatness, seems inclined to pursue the same path of improvement. "Since the marshes have been drained, the air of the Piræus appears to be as wholesome as that of Athens itself."—(Brandes) Intelligence from Greece, in German, Lips. 1842).

number of sick, and the ratio of mortality, have progressively become less and less; and spots that were formerly shunned as if they had been possessed by one of the worms or dragons of the old world of fable, may sometimes now be visited for their salubrity.

Dysentery used to be a disease extensively prevalent, and extremely fatal. It is one of the maladies, however, which is now actually of the rarest occurrence among us, and when a case does present itself it is rarely looked upon as dangerous*. This happy change is unquestionably due rather to the general improvement of the sanitary state of the community, than to the absence of any epidemical influence—unless, indeed, the presumed influence be regarded as synonymous with the neglect of every measure that conduces to the health of man, such as thorough drainage, wholesome food†, good water, and pure air, which indeed is the right interpretation of the term.

The *Asiatic cholera*, this singular product of the climatic and national elements of India, fell upon the countries of Europe as a new disease. But even in its sudden outbreak and gradual disappearance we had evidence of the influence and importance of the more highly civilized condition of our citizen-life. It seemed that it was only when favoured by transient states of political disturbance, or hostility between neighbouring nations, that it became possible for this scourge to pass the bounds that were prescribed to it. The success of the pains which the governments of Germany took to keep off the evil in its approaches will remain imperishably written in the history of its European progress, and afford ample proof of the importance of well-concerted and energetic measures of precaution‡.

* Forty years ago, Heberden could say that there is scarcely any fact deducible from the bills of mortality more worthy the attention of physicians than the gradual decline of the dysentery. From 1700 to 1710, the average annual mortality from this disease was 1,070, from 1750 to 1760 it was 110, from 1730 to 1800 it amounted to no more than 20.

† In the year 1835, dysentery prevailed in the circle of Königsberg to a great extent. In one village, of 26 who were attacked, one-half only escaped alive. But this was a year of great scarcity, and it was found that the people to make their flour go further had mixed it largely with the pollen of the male catkin of the hazel bush.—Sanatory Report of the Med. College of Königsberg, 1837, (in German).

‡ See particularly Dr. W. Wagner's account of the progress of cholera in the Prussian states, from official sources. Berlin, 1832. (in German).

first against the invasion and then against the extension of pestilence; for here, as elsewhere, it was found possible in numerous instances, by steadily enforcing the measures of medical police that had been determined on, particularly by isolating the sick, and carefully purifying the houses in which the disease had broken out, to nip the mischief in the bud*.

At the time of the cholera, both when the disease was imminent, and when it had broken out, the humanity and good sense of the community were awakened in a remarkable manner—the poor, the miserable, and the vicious, were all alike cared for; the inmost recesses of poverty, wretchedness, and filth, were penetrated, and such measures of lustration enforced, as have had their influence upon the health of the communities up to the present day; even as the snow storm that perchance overwhelms the solitary wanderer is pregnant with vernal leaf, and summer blossom, and autumn fruit, and life and joy, to all besides, so cholera may fairly be said to have done good rather than mischief in the European countries which it visited: if it have failed of the good which it ought to have done, it is only because men have neglected the salutary lesson they ought to have learned from its visit.

It is impossible to estimate at its full value the zeal and self-devotion of the whole of the medical profession in the

course of this great epidemic visitation; they never in a single instance shrank from the responsible, and, as they were generally held, dangerous duties which they felt to have devolved upon them; but, backed by the civic authorities and the police, shewed themselves conspicuously, as they ever are privately and unostentatiously, at the head of every movement that has the well-being and the improvement of mankind for its object. Truly and well did Tullius say, that "man never shewed more like the gods than in succouring his fellow-man." But the medical profession has, if possible, still higher destinies; it is even less interesting to individuals than to communities; it, in fact, serves the statesman and philanthropist as their guide in every effort to improve the physical and moral condition of mankind. Investigating the causes of disease and inefficiency, of premature decay and death, it indicates the means of averting these, or making them ineffectual; and so, without ever recurring to medicine in the vulgar sense, it prolongs life, and adds to the sum of enjoyment during the tenure of existence. It is in this direction that the enlightened member of the medical profession has especial claims upon the consideration of the state; it is with such grand ends in view as the general health and efficiency, that the state should shew itself solicitous to secure the highest possible amount of acquirement in the body of its medical practitioners.

Sea scurvy might be taken as a kind of unquestionable evidence that it rests with the future practitioner to discover and rightly to use proper means, in order not only to disarm the sorest bodily infirmities of their power, but even to put an end to them entirely. The ravages of sea scurvy in the navies of former times were frightful; in the present day the disease is unknown in every well-appointed ship. The orders of the Admiralty, that every vessel destined for sea during more than a certain very limited time, should be furnished with a quantity of lemon juice*, has made it possible to send

* In former times, probably, no question would have been raised as to the contagious nature of cholera. In these days nothing passes unquestioned; so that the contagious or non-contagious nature of cholera was soon the subject of active discussion among medical men. My esteemed friend seems a contagionist: in England, and in France, the non-contagionists may be said to have put the contagionists fairly hors de combat; not 1 in 20 was found at last with a word to say in favour of the contagiousness of cholera; 19 in 20, on the contrary, were fully satisfied that the disease was not contagious. The disease in fact, when at the height, showed itself in so many points simultaneously, that it was altogether impossible to explain its appearance upon the idea of contagion: to have attempted to do so would have been no less unreasonable than to refer influenza or hay-fever to contagion. In the course of a very few days the whole of Paris was invaded: between sunset one evening, and sun-rise next morning, the disease had begun and ended in several thousand instances—they that were alive and well the one day were lifeless corpses the next. In spite of the freedom and rapidity of our intercourse in England, many towns escaped entirely; in towns and districts where the disease presented itself, the majority of the cases were merely sporadic—half a dozen or more persons were seized and lost, the rest of the community remained unaffected.—*Enc. Ed.*

* Blane informs us (op. cit. p. 4), that in the year 1793, (the first in which the general supply of lemon juice took place) the sickness, instead of decreasing, gradually fell *per saltum*. John Woodfall, who lived for a time in the town of Stude, towards the end of the 16th century, was the first who indicated the curative powers of lemon juice.—See his *Surgeon's Mate*, Lond. 1617.

expeditions to the extreme north and south, and to maintain the companies through the rigours of a succession of arctic winters, without a single individual among them suffering from scurvy. The disease may be said literally to have disappeared from the British navy, in which every thing that science and foresight can do to secure the health and comfort of the crews is done. Even in the merchant service scurvy is extremely rare; instances, however, do every now and then occur, in which, through sordid villany, vessels are sent to sea inadequately found in wholesome provisions and needful medicines—to say nothing of their being without any medical man on board: there, and under such circumstances, does the disease still break out. But these cases are no more than exceptions to the general rule. In the naval hospitals of England sea scurvy will be looked for in vain*; he who would learn what the disease was in former times, must go to books, or to countries where the lights and usages of civilized life have but partially penetrated*.

* In my visit to England, in 1841, I myself inquired for the disease in vain, as I have said in my "Recollections of England," Brunswick, 1842. [There is, nevertheless, every now and then an opportunity of seeing scurvy in the River Hospital Ship "Dreadnought." It would be wonderful, indeed, if out of the multitude of ships of all nations that crowd the Thames, some one did not occasionally put in tempest lost, wind bound, detained from her port long beyond the expected time, with her crew suffering from scurvy. The poorer class of merchant ships, however, are known often to be very inadequately provided for the long voyages they have before them; and from what the medical officers of the Dreadnought occasionally see, as well as from what has transpired upon other occasions, it is not going too far to say, that some better measure of police than any that may perchance exist seems imperatively demanded in this direction.—*Eng. Ed.*]

† Two hundred years ago scurvy was among the most frequent diseases in London. Graunt, in his *Observations upon the Bills of Mortality*, speaks of it as among "the casualties that bear a constant proportion unto the whole number of burials." The disease has now disappeared. In Paris scurvy is also so rare a disease, that Andral says (*Revue de Médecine Pathologique*, Paris, 1843):—"Les scorbutiques bien caractérisés sont si rares à Paris, que pendant long-temps j'en avais été réduit à une simple conjecture sur l'état du sang dans cette maladie." In Archangel, however, scurvy appears to be still endemic among the poorer classes (Richter, *Topography of Archangel*, p. 121, in German.)

[Lord Anson, and other navigators and writers on scurvy after him, indicated the cochlearia or scurvy grass, cabbage, and green vegetables generally, as the grand restoratives from scurvy. The potato has been lately pointed out as even more effectual, both in a prophylactic and restorative point of view. Probably the universal use

Leprosy was at once the most dreaded and dreadful disease of antiquity and the middle ages, when it seemed to have spared no rank or condition of society*. The disease appears to linger endemically at this time in one isolated corner of the coast of Norway†; from all the other countries of Europe it has vanished. In former ages thousands of leper-houses were found necessary to receive the multitudes who suffered from this disease in its most aggravated forms, and when it was held contagious‡; when a case of Greek leprosy occurs in one of our hospitals now, all the world of medical men crowd to see it, probably for the first and last time in their lives§; and then the subject of the disease is almost always a negro, or a man of mixed blood, and a native of some of the warmer countries of the earth. The extension of leprosy over Europe in the middle ages was ascribed to the return of the crusaders to their homes, by whom it was generally believed to have been imported. If this were actually the case, it is certain that European civilization has cast out the evil again, and that, with the remarkable exception mentioned, the disease is now only encountered in lands where medical science stagnates, and where the indolence, the superstition, and the ig-

of this excellent root is the main though unsuspected cause of the immunity we now enjoy, both afloat and ashore, from scurvy.—*Eng. Ed.*]

* The Roman Emperors, Augustus and Tiberius, both bore traces of leprosy upon their persons (Vide Hensler on the Western or Greek Leprosy, in German, Hamburg, 1790, p. 251.)

† See a brief but interesting notice of this disease, by M. Danielssen of Bergen, in *Comptes Rendus*, No. 14, 1844, and *Lond. Med. Gazette*, June 7, 1844.—*Eng. Ed.*

‡ In the 13th century the number of leper-houses in Europe was estimated at about 20,000. (Vide Möhsen, *Account of a Berlin Collection of Medals*, vol. ii. p. 281, in German.)

[See also the interesting papers of Dr. Simpson, of Edinburgh, on Leprosy and Leper Hospitals in Scotland and England, published in the *Edinburgh Med. and Surg. Journal*, vol. lvi. p. 301, and vol. lvii. pp. 121 and 394. He gives the localities of upwards of 100 leper hospitals in these countries.—*Eng. Ed.*]

§ Riecke, in his *Contributions* (p. 22), says that in the course of twelve years nearly twenty cases of elephantiasis had been observed at the surgical clinicum of Tübingen.

[If the diagnosis were well established in these cases, the above fact would indicate some local influence, in or near the town of Tübingen, favourable to the production of the disease. I have not seen any thing of the same kind stated in connection with any other hospital, either in England or the Continent. I have myself several times seen the Arabian elephantiasis, *Elephantiasis Arabica*, in London, both in hospital and in private practice; but this is a very different disease from the Greek leprosy, *Eleph. Græca*.—*Eng. Ed.*]

norance of the inhabitants, still consent to give it room to exist, and material to feed upon.

Small-pox.—It is doubtful whether this loathsome disease was known to the ancients or not; for many centuries, in modern times, at all events, it was reckoned as among the inevitable calamities of the human kind: since the discovery and general practice of vaccination, however, it has almost disappeared in some districts, and has diminished notably in its destructive powers in all. Among all the benefits which humanity ever received through man, no greater, or more important in its consequences, can be named than this. Till EDWARD JENNER lived, one-twelfth of the whole human family was swept away by the pestilence of small-pox, and a much larger proportion was left bereft of sight, or shattered in constitution and hideously scarred, as evidences of its destructive power. Jenner's immortal discovery immediately, and as if by magic, set bounds to the pestilence. The number of cases, whether of genuine or of modified small-pox, which have appeared since Jenner's time, cannot be compared with the host that presented themselves previously. Even in the period when the influence of vaccination was less understood than it is at present, when content with a single operation at the beginning of life, and this often imperfectly performed, all kind of reasonable and necessary precautions against contamination were neglected, the mortality from small-pox was still infinitely less than it used to be in former years*. In all those states which have taken the business of vaccination into their own hands, in which ample supplies of active virus are carefully provided, and where revaccination is encouraged in every possible way, small-pox may be confidently, and without any exaggeration, said no longer to exist as a formidable disease†. Vaccination is, indeed,

* Even in Archangel, from 1822 to 1826 inclusive, no more than a couple of cases of small-pox were observed at the Marine Hospital; the number seen in the Civil Hospital, during the same time, was only six! (Vide Richter, op. cit. Table, p. 149.)

† In Prussia, for instance, between 1820 and 1834, of one million of deaths, 8,191 were from small-pox, or 1 in 122 (Hoffmann, in Prussian Medical Gazette, 1835, No. 45). [In England, our admirable returns shew us that small-pox was actually less destructive in 1841 than either measles, scarlatina, or hooping-cough. In this year, 14,161 died of scarlatina, and only 6,366 of small-pox!—*Eng. Ed.*]

a brilliant illustration of the advantages of civilization; it is one of the precious fruits that spring from human thought and inquiry; it is one of the costly prizes won by hearkening, with tutored ears, to the still, small, accents of nature, which escape the uncultivated sense entirely. The health and life of millions, without sacrifice at the shrine of pain, and without denial, are assured through its means. This great discovery sprung complete from the labours of Jenner, like another Minerva in arms from the brain of Jove! and soon, like Pallas, to instruct, did it set out, over the face of the habitable globe, on its God-like mission to save; nor did it once pause till it had penetrated to the helpless Indian under the shadow of the everlasting forest, and to the far Cathay! Thus does civilization, with her blessings, come to influence the savage and the semi-barbarian; favourably impressed through obvious advantages, he is prepared for the reception of the other less manifest, but not less momentous, privileges and immunities that follow in her train*.

Is it necessary to adduce other instances, in order to prove that civilization not only does not add to the number, or increase the severity of diseases, but, on the contrary, that its

* There is extant a letter from the five nations (North American) to Jenner, in which the following beautiful passage occurs: "We shall not fail to teach our children to speak the name of Jenner, and to thank the Great Spirit for bestowing upon him so much wisdom and so much goodness." (Life of Jenner, by J. Baron, vol. ii. p. 103.) Halford, in his discourse "on some of the results of the successful practice of physic," advocates the propriety of sending medical men, as missionaries, into uncivilized countries, knowing full well that the feeling of thankfulness for physical good was the surest passport to the understanding and the heart. It was Gabriel Boughton, the surgeon, who paved the way to the establishment of the East India Company, and who, by doing so, threw open the vast peninsula of Hindostan to the civilized world. The medical officers of the East India Company's service have, in fact, been at all times a principal bond of union between the natives of India and the British (see Mill's History of British India, vol. i. p. 170).

French missionaries had the honour of introducing lancets from England, charged with cow-pock lymph, and a translation into the Chinese tongue, by Sir G. Staunton, of Jenner's pamphlet on vaccination, into Peking, the capital of China; and Mr. John Barrow soon after wrote to Jenner to inform him that his work, in Chinese, had actually been published in Canton, and that the practice of vaccination had already made great progress (Baron's Life of Jenner, vol. ii. p. 85). "Thus," he remarks, "the English, at length, have established their claim on the gratitude of the Chinese."

invariable effect is to lessen their force, and frequently to vanquish them entirely? Surely it is not. Almost every one of the innumerable host of ills that assail mankind, when searched into in its causes and connections, gives us new assurance of this consolatory truth. In the same proportion as the arts and sciences, as morals and true refinement, advance and approach perfection, are the means multiplied by which human life is assured against enemies both from within and from without. True knowledge and true good go hand in hand together. The old Grecian Mythus proclaimed light to be joy, to be bliss also; Phœbus Apollo, who illumined the world, was likewise the healer; to him was the all-hail given, and the psalm, the song at once of joy and thanksgiving, upraised. What antiquity, in mythic foreboding, announced, in the lapse of millenniums is made manifest. The more humanity attains to the knowledge and the evolution of all its capabilities, the more surely will the full harmony of corporeal existence also be unfolded. It may, with every reason, be said, therefore, that intelligence is not only synonymous with moral power, but also with bodily health. Access to the treasures of mind is denied to none; the art of printing, and our educational institutions, place participation in the highest good within reach of all. Medicine has not lagged behind the other evangelists of enlightened humanity; on the contrary, she has ever been foremost in the race, where the object was to enlighten and to raise; and as her purpose has still been to root out disease, and to lessen its power—to help the sick and the suffering, to confirm the healthy and the strong—so has she also striven to make her truths common property, irrefragable evidences of civilization.

**REPORT
ON THE
ROYAL MATERNITY CHARITY.**

By F. H. RAMSBOTHAM, M.D.

(For the London Medical Gazette.)

[Continued from p. 281.]

DURING the year 1837, there were delivered in the Eastern District of the Royal Maternity Charity, under

the superintendence of Dr. F. H. Ramsbotham,—

2140 women—Of which cases,

26 were twins—about one in every 82½ cases: of these, in 12 cases both heads presented; in 11 the head and breech or some part of the lower extremities; in 1 both breech or some part of the lower extremities; and in 2 the head and shoulder. In 7 of these cases both children were boys; in 8 both girls; and in 11 they were of different sexes. One of them was premature.

1085 children were males.

1081 children were females.

2113 were presentations of some part of the head, of which, 10 were face-presentations—about one in every 216½ births; and one was an ear presentation.

40 were presentations of the breech, or some part of the lower extremities—about 1 in every 54 births; of these 13 were twins.

13 were transverse presentations—about one in every 166½ births; of these 2 were the second of twins, one was born still, the other living, 53 hours after the birth of the first child. In one case the fœtus was expelled doubled, or by the “spontaneous evolution,” at full time, still. Four were premature, and all passed doubled; two of these cases were at 7 months; in one labour was voluntarily induced, the pelvis being narrow at the brim; the presentation was the side. The other two were at five months; one was an abdominal presentation, and there was hæmorrhage before delivery. All these children were born dead. With two the placenta presented at the os uteri; one of these children was extracted living; the other dead. In the latter case the woman went on very well for a month; when she put herself in a violent passion, and died suddenly. In the other four cases the children were born dead. One of these women also died on the evening of her delivery; being perfectly exhausted from the want of the common necessaries of life. The operation of version was performed in all the cases except the five just detailed.

In 3 the placenta was implanted entirely over the os uteri—about one in every 713 cases; the patients were all delivered by “turning;” in 2 the shoulder was at the brim; 2 of the children were born dead; 1 living;

two of the women did well; the other died suddenly as stated above.

10 were complicated with alarming hæmorrhage before delivery, *not* the result of placental presentation—one in every 214 cases. Three of these children only were born alive; one presented with the feet; one was a case of twins at 6 months, both born dead; 3 others were premature; one at 5 months, the abdomen presented; the other two about 7 months. None were delivered artificially, and in most of the cases the membranes were ruptured with manifest advantage.

In 16 the placenta was retained within the uterus, either by atony, or irregular contraction of the uterine fibres, or by morbid adhesion between the uterine and placental surfaces—one in about every 134 cases. One woman died from the effects of hæmorrhage on the third day; the case was premature.

1 was complicated with violent hæmorrhage immediately after the natural expulsion of the placenta; it was restrained, however, by common means, and the patient did well.

2 women were delivered by craniotomy—one in every 1070 cases. One had had children before, and always lingering labours: I had once before delivered her by craniotomy: although the head was in the pelvis, as the child was putrid I thought it better to open the head than to attempt delivery by the forceps. In the other case the child was also putrid in the highest degree, and though a portion of the scalp was external, I perforated the skull; this was her first child, and there was a slight deformity of the pelvis. Both the women recovered.

3 were delivered by the forceps—about one in every 713 cases; one by the long, two by the short instrument; where the long was employed it was the woman's ninth child; she always had had lingering labours in consequence of her pelvis being distorted at the brim. When I saw her the membranes had been broken 20 hours: the pains were very strong, and the head had made no advance for many hours. The face was looking towards the right groin; the chief part of the head was above the brim, and the right ear could with difficulty be reached behind the left groin. I applied the long forceps, one blade over the left brow, and the

other behind the right ear, and delivered in about 20 minutes. The head was very much elongated. The child was born living. One of the other children was also born living: with the last the funis prolapsed, and the child was born dead. All the women recovered.

3 were complicated with puerperal convulsions; one before, (the child was born naturally, dead), and two after delivery—about one in every 713 cases: one occurred 12 hours after delivery. Both these women did well. The other 10 days after delivery: the attack occurred on Christmas evening: the woman was as well as could be: she had eaten a hearty dinner, had taken some beer, and was enjoying herself with her friends very injudiciously, when at 9 o'clock she was seized with apoplexy, and one convulsion took place: she continued perfectly comatose, and died at 12 the same night.

In 1 case premature labour was induced; the child presented with the side, and was expelled doubled, dead.

In 1 case the uterus ruptured itself during labour. This was the patient's fourth child; all her previous labours had been lingering. The membranes had been broken about 40 hours when I first saw her, but she had had no strong pains: the midwife became alarmed by symptoms of exhaustion rather suddenly occurring. I found her cold, vomiting a black coffee-ground-like matter, and with a sunken, death-like countenance. I immediately detected a laceration in the anterior part of the cervix uteri, and the feet presenting. I extracted the child, but was obliged to perforate the head. I afterwards introduced my hand for the removal of the placenta, which I found lying loose among the intestines; it, as well as the child's body, having escaped into the abdominal cavity. The child was putrid. I was assured that the head had originally presented; so that it, as well as the trunk, must have escaped into the abdomen, and given an opportunity for the feet to fall, as it were, down to the brim of the pelvis. I have known the same change in the position of the child occur in another case after laceration of the cervix uteri. She died in 8 hours. I could not learn that this laceration was attended with any immediate prominent symptoms; and neither the mid-

wife nor any body about her had the least idea when it occurred. On opening the body next day, we found about six ounces of coagulated blood in the cavity of the abdomen; there was a rent six inches in length in the anterior part of the cervix uteri, horizontal in direction through the greater part of its extent, and then proceeding upwards towards the left broad ligament: the part of the uterus in the neighbourhood of the rent gave way on the slightest force being applied, and the whole organ was much softer than is usual. A great portion of the small intestines was almost black, and there were evident traces of abdominal inflammation of some standing. The pelvis in its conjugate diameter at the brim measured rather less than three inches.

13 women died either from puerperal causes, or within the puerperal month—being about one in every 165 cases. Only 8 however, as a consequence of labour—or one in every 267½ cases; for three died of phthisis; one of influenza on the 8th day, and one of typhus on the 30th day after delivery.

2079 children were born alive.

87 were still-born—about one in every 25 births.

Of the Deaths,

1 was on the third day after delivery, from hæmorrhage consequent on a strongly adherent placenta.

1 a month after delivery under placental presentation. The woman died suddenly, in consequence of putting herself into a violent passion. She appeared to have recovered completely from her labour.

1 from apoplexy ten days after delivery, in consequence of excess as stated in the paragraph "convulsions."

1 eight hours after delivery, under a ruptured uterus.

1 the day after a lingering labour.

1 a few hours after delivery under a shoulder presentation; the woman was perfectly exhausted for want of necessities.

1 from peritonitis on the fourth day after delivery.

1 from influenza on the eighth day after delivery; she had been ill with the disease for many weeks.

1 from pneumonia in the fourth week after labour.

1 from typhus fever 30 days after labour.

3 from confirmed phthisis; one 5, another 10 days after delivery; and the other 3 weeks.

Of the still-born children,

22 were premature.

15 were putrid, at full time, or nearly so.

5 were presentations of the breech or inferior extremities, at full time or nearly so.

6 were transverse presentations, at full time or nearly so.

With 1 premature labour was induced. The side presented.

2 were delivered by craniotomy.

2 under placental presentation; one was a transverse case.

4 after alarming accidental hæmorrhage.

2 under convulsions.

2 under very lingering labour.

With 8 the funis prolapsed by the side of the head; one was delivered by the forceps.

3 after the mothers had suffered some severe accident near their full time.

1 after rupture of the uterus.

With 1 the mother was dropsical.

1 was a face presentation.

1 was monstrous.

1 was ascitic.

10 were at full time, not putrid, nor delivered by art, there being no evident external cause to account for the calamity.

PUERPERAL CONVULSIONS IN A TWIN CASE.

ARTIFICIAL DELIVERY; COUNTER-IRRITATION TO SACRUM; ANTI-SPASMODIC ENEMATA; RECOVERY.

By ROBERT PATERSON, Esq.

Surgeon, Glasgow.

(For the London Medical Gazette.)

At 1 A.M. Sept. 15, 1843, I was summoned to attend Mrs. S. æt. 27, in labour with her first child. I found that labour pains had existed about three hours; the os uteri, scarcely the size of a crown-piece, was rigid; the presentation footling; the membranes entire. The patient complained of headache, from which she had suffered much during the latter stage of pregnancy. The atmosphere was very hot and oppressive. At half-past two, during a pain, she was seized with a severe

convulsion, which lasted five minutes. The head and shoulders were immediately elevated, and 30 oz. of blood drawn from the arm in a full stream; the hair was removed from the scalp, and cold applied. Insensibility remained, and she was soon attacked with another frightful convulsion, when 30 oz. more blood were taken away, as the pulse was still good. Delivery was now decided upon; the membranes ruptured, the feet brought down, and the head extracted with the aid of the forceps. While engaged in this procedure, a third fit occurred, during which all attempts at delivery were necessarily suspended. The child was a male, still-born, but might probably have been resuscitated by a continuance of the proper measures, which were unfortunately interrupted by the occurrence of a fourth convulsion. A second child was now discovered presenting with the head. The catheter was passed, and the membranes ruptured by the hand, when a powerful pain brought the head down within reach of the forceps. The fifth fit now occurred. The patient was again bled to 20 oz. and as soon as the fit was over the forceps were applied, and a female child extracted. This was also still, but by much perseverance was resuscitated. The placenta came away easily, with few clots, and the delivery was completed by 4 A.M. On attempting to apply the usual bandage, a sixth fit took place. Mr. Lyon was summoned in consultation, and in about half an hour saw the patient. Between 10 or 12 oz. more blood were removed; in less than twenty minutes a seventh fit occurred. The patient now lay in a state of apoplectic stupor; the lips were puffed out with each inspiration, as in smoking; the pulse was hurried and small, and sometimes scarcely perceptible; the extremities and surface generally cold, and covered with a clammy perspiration. Sinapisms were applied to the legs, and a stimulating clyster exhibited. At 7 A.M. reaction had taken place; the sinapisms had acted well, and the enema brought away a copious offensive dejection; cold was continued to the head, and two grains of calomel were put into the mouth. At 2 P.M. as she had no return of the fits, the bandage was attempted to be applied, when the eighth fit occurred. On consultation, cupping was thought inadvisable, but

a blister was directed for the scalp, mercurial frictions to the arms and thighs, and calomel grs. ij. every hour. By 6 P.M. five more fits had occurred with unabated severity; the heart could not be heard beating, and the respiration became inaudible. The blister was removed from the scalp, the legs and feet enveloped in sinapisms, the lumbar and sacral regions rubbed with spirits of turpentine, and the sacrum covered with a blister. An enema of hyoscyamus, valerian, and assafoetida, (3j of the tinctures of each) was administered. The respiration soon became more audible, but the pulse in the extremities could not be detected till 10 P.M.

16th, 5 A.M.—No return of fits; continues unconscious; has been very restless; blister has risen well; bowels are acting involuntarily; has had three clysters. To continue the calomel every two hours—the mercurial friction to the thighs only, and cold to the head. She now gradually recovered, but remained unconscious till 56 hours had elapsed from the first attack. She suffered acutely from pulsative headache and salivation, but was able to leave her bed in eight days, and returned to domestic duties at the end of a fortnight.

REMARKS.—In this case I believe that I had to contend with sanguineous apoplexy, which fortunately proved to be only of a congestive character. While I dare not regret the extent to which blood-letting was carried, for it is impossible to say that recovery would have taken place had less blood been abstracted, yet I strongly suspect less might have sufficed. Notwithstanding the enormous quantity removed, the fits did not remit, but increased in frequency and violence till 6 P.M., ten hours after the last bleeding, and during which the pulse continued small and feeble. The blister to the scalp, I conceive, proved injurious rather than beneficial, as it was followed by more determination to the brain, evinced by greater lividity of the countenance in the intervals, and a more rapid succession of the fits. It was, in fact, when all hope appeared to have fled, and the patient was regarded as irrecoverably lost, that counter-irritation over the sacrum was adopted, together with injections composed of the Tinctures of Hyoscyamus, Assafoetida, and Valerian,

(aa. xi.) and I hesitate not to state that every step in the onward progress of the treatment proved abortive till the uterine system was specially acted upon. By the previous application of turpentine, the blister to the sacrum acted pretty efficaciously in three hours, and from the immediate results, I feel persuaded that, if earlier employed, the patient would have been spared much suffering, and relieved from the agonizing pulsative headaches and other ills attendant upon an extensive loss of blood.

As it seems pretty certain now that profuse blood-letting does not at all times arrest puerperal convulsions, caution must be exercised lest the abstraction of blood be carried so far as to endanger life. Out of 54 cases recorded by Dr. Lee, 19 deaths occurred, in many of which bleeding was largely resorted to; while in the 35 recoveries the majority were bled sparingly. Believing the primary irritation to be seated in the nervous ganglia of the uterus—ganglia which enlarge with the coats, blood-vessels, and absorbents during pregnancy, as demonstrated by Dr. Lee—I strongly recommend counter-irritation over the sacrum, in conjunction with soothing and antispasmodic enemata, after the primary and indispensable measures of bleeding, delivery, and free evacuation of the bowels. The employment of counter-irritation I consider as entirely new, and that of anodyne enemata to be barely mentioned, and not insisted upon by the best obstetrical writers.

ON CONSTITUTIONAL IRRITATION OR GENERAL DISTURBANCE.

By T. WILKINSON KING, F.R.C.S.E.

[Continued from page 264.]

Organizable (?) deposits are but growths.—Symmetry, humoral, &c.—Some analysis of depression, and of sympathy, general and contiguous.

New growths.—As to the idea of a clot of blood or a mass of fibrin, plastic lymph, or any thing of the kind, becoming organized, that is to say, having vessels shoot into it to make it a living tissue, we freely confess our ignorance, and that we are averse to such doctrine.

When a membranous vascular layer gradually extends itself over the albumen, or over the yolk of an egg in incubation, we conceive it to be simply

new growth facilitated by these animal fluids and their membranes. Mr. Hunter's view of the vitality of the egg is modified by the consideration that the impregnating germ is the only source of living actions, and that vessels from the chick are but as roots in the earth.

It remains to be shown, that besides simple repair of injured organized tissue, any other vascular formation can take place than by simple growth. This, no doubt, microscopically, is in part by vascular shoots or arches. It is said that the museum at Guy's presents instances of solids, cognizable by common vision, *becoming* organized; but our perception has been hitherto confined to vascular growths, and we venture to observe that fifty doubtful examples are no better proof than one. In the end of phthisis, a new delicate vascular layer may rapidly form over a hemisphere of the brain, but the morbid anatomist seeing this in every gradation of its formation, must conclude that it is merely modified growth. This organization is totally different from what has been called plastic effusion, and organizable lymph or fibrin. We know nothing of *organizable deposits*. The course of deposits is totally different from that of living tissues, for though, like blood, they may not decompose, they can only, so to speak, dry up, or be more or less completely washed away or absorbed. Cartilaginous serous membrane is slow anormal hypertrophy. Cellular adhesions are produced by vascular inosculations, of serous surfaces, becoming stretched, perhaps to half a yard, in the abdomen. All mere fibrinous or albuminous masses, films, webs, and layers, are but coagulations from fluid effusions, and though found in many different forms and stages, and even bound up in vascular growth, they are neither organized nor organizable. Joints and blood-vessels, and mucous passages, present various true polypoid growths (simple and malignant); but a clot of blood or isolated mass of any kind (differing from the tip of the finger) cannot *begin* to receive blood-vessels. In all this we do not pretend to encroach on the beautiful observations of our admired microscopists, and we hold that in turn these observers must not infer too much by comparing small things with great.

A slough or caries, like a nail, may

adhere to organized parts, and though certain tissues may seem more particularly extra-vascular, it must be apparent that all living tissues are essentially external to their capillaries. Inflammatory products and new growths appear to present themselves in parallel gradations to the preceding. Strumous matter is at one time mere deposit; at another, dead organization. Cancerous tuber may die, and be long shut up as blood or fibrin, but the rise and arrest or progression of even the most local of the foregoing alterations, are inseparably dependent on the general state of the system.

With a certain condition of the body, organized membranes spread within a joint rapidly and copiously. They spring and grow from vascular parts, and creep only where repose or the absence of pressure permits, in layers or serpentine bands; but in themselves, properly considered, they most resemble, as we think, granulations tending to fill up, though ill and feebly, a cavity where the forces which should resist such changes are wanting.

Symmetry in irritations.—The symmetrical arrangement apparent in diseases is better explained by reference to humoral, physical, and nervous principles combined.

The ingenious and original study of Dr. W. Budd, on "Diseases which affect corresponding parts of the body in a symmetric manner (Med. and Chir. Trans. vol. xxv.) is a valuable contribution to *humoral* pathology. The paper of another able investigator, Mr. Paget, (in the same volume) serves to illustrate both *physical* and *humoral* agencies. The researches of M. Bizot, (Mém. de la Société, vol. i.) have a similar use. Illustrations of the subject abound in every museum, and in every ward, and even the oculist, dentist, aurist, and chiropodist, see very much of morbid symmetry.

We suppose that the symmetric acts of the morbid body, as well as of the healthy body, indicate principally a humoral agency. There is a primitive disorder in the blood, as the general cause from which local changes spring. The special or local causes of such symmetrical developments are distinct and various. The whole form of the femur or of the little toe is determined by the tensions and pressures (and even by the vibrations as to cancelli) that the part grows under. The size of two

corresponding parts is in relation to their exercises, and to their distance from the nutrient source. Their degree also of development and vigour depends on the activity and healthfulness of the sanguineous supplies.

The processes of modelling and absorption depend on diminutions of pressure or disuse, and also on the defects of nutrition, and as a complex series of causes which give rise to normal symmetry are liable to similar perversion in opposite parts, so the anomalous symmetry may be produced.

As to the individual causes of symmetry, they appear most of them very simple. Mr. Paget justly says, "the same influence on two similar parts will produce in both the same results." We see these influences regulating the equal growth of limbs. They are external, as temperature; or internal, as, for instance, the motions of the part, its humoral supplies, and its innervation. We have symmetry, in short, affected from the first period of development, by mechanical, humoral, and nervous functions.

The mere fact of attraction of affinity at insensible distances would seem to be sufficient explanation of the regular form of crystals. The molecular attractions of our bodies may be said to be restricted within a circle of about three feet radius, or in the fœtus of less than one line; and the vital acts are necessarily proportioned to the material resources within a body, and to the influences operating externally on each part, as on the whole.

The first point of bone in the body of a vertebra is subjected to symmetric forces, and therefore to symmetric growth, whilst that in a patella has, so to speak, half of such forces to regulate its form.

To regard symmetric irritation as a law, would seem even as a final cause to be an unsatisfactory idea, inasmuch as such law is *always* broken, for *exact* symmetry never yet has been established, either in health or in disease; and the reason of this of course must be, that the forces of causation are almost invariably non-symmetric in some degree, as in the differences between the right hand and the left. It is to be remarked, that the want of precise symmetry is manifest in all the drawings of Dr. Budd and Mr. Paget.

With enough of fluids and of power

to commence the basis of two legs and arms, the equivalent of matter or of strength for an extra digit may be wanting.

The further symmetric course of events we may illustrate by reference to very common circumstances.

A blow on the vertex fractures the calvaria symmetrically; the jaw grows, wastes, or luxates, symmetrically. The form and circumstances of the patellæ decide that both shall break simultaneously. Disproportionate nutrition makes the gastrocnemii on each side tear their tendons, or become cramped after exertion. The same exercises of the two knees induce symmetric ganglia on the patellæ, while the state of the blood determines that the tumors shall be fluid or dense, and that now they inflame simultaneously, and now are quiescent together. The miner's elbow ganglion is caused by undue pressure on one arm, and aggravated by undue reparative acts.

Instances of symmetry by deficiency in the blood are seen in pallor, cold feet, chilblain, frost-bite, gangrene, hectic flush, ulceration, lupus, and various atrophies and absorptions, as of the neck of the femur, and in all senile decay.

Symmetry of plethora is seen in florid or fat persons, and in various hypertrophies, but we understand that if one side takes on hypertrophy, the means of hypertrophy may be there all expended. This and the converse will find wide application in pathology. Symmetries resulting from sanguineous deteriorations occur in anasarca, onychia, in scurvy, and in simple fever also. The like seem at times to depend on the excess of certain materials in the blood, as the matter of warts and exostoses. Cancer or tubercle, with bad elements of nutrition, affects the two thigh bones, or the two lungs. Poisonous fish may cause symmetric eruptions. Argenti nitras acts on all the skin; lead on all the muscles, but most on those which are most used by the painter*. The materials of gout and rheumatism, it is true, are said to fly here and there, but we think this is far too simple an idea;

for the attendant inflammation, tumefaction, softening, adventitious deposits, and reparations, are complex affairs, the stages of which are nowise defined (the difficulties are not explained) by the mere presence or absence of so much urate or lithate in the system.

If we find the biceps of one arm with three heads, we know that we may expect something similar in the other member. We think, too, that such cases belong more particularly to the muscular diathesis. So, on the other hand, we find muscles variously deficient in pairs, and the like also of most tissues. In lepra the materials of cuticle appear to be in excess, and also deteriorated. So in ichthyosis, and that remarkable and rare hide-bound* state of the fœtus in utero, in which the skin is nearly half an inch thick, cracking in the flexures of joints, &c. here and there symmetrically, and all the orifices projecting. In fact, there may be a proneness, from the state of the blood, nerves, and outward circumstances, to any affection of any one tissue, and the causes may or may not operate more or less universally, locally, or symmetrically.

A patient of our own, a lady of about fifty years of age, of very dark complexion, and rather marked hypertrophic tendencies, has had for years four whitish ovoid smooth warts (condylo-matous) about the size of half a pea, but flatter, placed symmetrically on the eye-lids, each one being about a quarter of an inch from the cilia and the inner canthus. The diathesis determines the nature of disorders—the nature of parts fixes their site. That psoriasis affects the palms and soles, and lepra the knees and elbows, is a consequence of the affinity between matters in the blood and skin, and of course of the similarity in structure and uses, and even in the accidents of the parts. The same applies to the changes in pairs of arteries. Particular parts suffer most by use, and the repair is simple, hypertrophic, atheromatous, or earthy, according to the state of the individual affected.

These views seem almost sufficient to explain all appearances of symmetry. They seem to point to the original cause of the first ossification in each os calcis, and even the anterior com-

* Dr. Budd, we think, is mistaken in supposing the flexors of the hand not affected. They being the stronger mass, the hand drops and the fingers bend, though the paralysis may not be complete. The disease is universal; the excess and manifestation are partial.

* See Guy's Museum.

mencement of cartilages, and so on wherever we can discover humoral and physical causes acting and commingling in natural events or in morbid irritations.

The history of *depression* may both derive light, and supply some, by being connected with our present study.

The explanation of the state of collapse is not likely to be very simple, or easily propounded; yet a series of plain and certain considerations will materially assist us in attaining a right knowledge of it.

Hæmorrhage, long abstinence, fatigue, or fear, induce a syncope, in which the diminished fulness of the blood-vessels seems the chief defect, *e. g.* the blanched cheek. Antimonial or other poisons in the blood, though they do not at once affect the quantity, must act, at least in part, in a similar manner; the relaxation of vessels, and of the heart, and the enfeebling of all the muscles, which thus fail to support the venous circulation, being essential physical circumstances of the case. The pain of colic, squeezed testis, or a crushed foot, have all something in common with fear; for (through the nerves of volition) the muscular system is relaxed as well as the vascular. We may have tremor as well as paleness and a cold surface.

A temporary concussion of the brain produces analogous effects, although the severity of the collapse may be less. Vomiting and involuntary micturition are here but incidental effects—parts of idiosyncrasies, and not of any one kind or cause of collapse.

With a blow on the shin the breathing may be almost arrested, and fear, or the accident just mentioned, may produce syncope; but to all these circumstances we do not know that it is necessary to attach more of agency than belongs to the cerebral perception and the control of the muscular system.

As to the blow on the epigastrium;—we think it right to doubt whether the *scrobiculus cordis* really received the violence in all or in most of the related cases. Even prize-fighters know that a blow on the belly is quite precise enough for the truth; we say it is especially so if it is to be made a subject of philosophical inference.

In the next place it should be remembered, as of great importance, that we become clearly and forcibly im-

pressed with the facts which prove the wonderful powers of endurance inherent in the really healthy body. We have adverted to cases of great lesion. Instances of slight shocks being injurious, and of greater shocks proving almost harmless, are well known. The following examples are of a different kind.

Extraordinary instances of human endurance, without latent physical consequences, are related by Dr. Schoepff, speaking of the inundation of Pesth, in 1838. "Thousands remained from twenty-four to forty-eight hours immersed in water, frequently without any shelter, and not seldom without nourishment." "The wife of a small tradesman, who but a few hours before had become the mother of a child, leapt out of bed on hearing the rush of water into the street, and having long toiled to save her little property, became at length immersed to her chin, when, securing a frenzied hold of the half-broken door, she clung to it till the dawn. She was rescued just twenty-eight hours after the birth of her child, and the infant found dead in her arms. Being removed to the protestant church, the unhappy mother spent four-and-twenty hours in constant movement and excitement, without changing her clothes or taking the slightest nourishment. On the following day she sank down exhausted, slept for six hours, and only complained, when she awoke, of excessive debility; she had no sensation of either hunger or thirst, and the food she swallowed seemed scarcely sufficient to sustain life. This was now the 17th of March; and by the 2d of April, though still weak and languid, she had recovered her health, and a week afterwards resumed her household duties. Physically, she had sustained no permanent injury; but she has never smiled since.

"On the same memorable 15th of March, the house of a labouring man suddenly gave way from roof to base, when he succeeded in clambering on a beam which had been only partially displaced. There he remained for fifty hours, without nourishment, or daring to yield to the desire to sleep which stole on him from the intensity of the cold. On being rescued, he was several times upset, for three days and nights suffered acute pain, and long resisted food; but he ultimately recovered, and now enjoys as perfect health as ever.

"An infant, eighteen months old, was rescued from its little bed, the water having risen to its chest, and did not suffer in the least from the exposure. Another had lain in its cot for two days and a night without nourishment; but was ultimately restored, and still lives. Many delicate women, long unable to walk, and some even to move, unassisted, far from suffering from the exertion to escape on the memorable night of the 15th, after a continued moral excitement of three days, recovered the health which had long been despaired of."

(To be continued.)

ON HERNIA,
OR
PROTRUSION OF THE INTER-
TEBRAL SUBSTANCE,
AS A CAUSE OF PARAPLEGIA.

To the Editor of the Medical Gazette.

SIR,
IN a clinical lecture on spinal affections, by Mr. C. Hawkins (MED. GAZ. May 17th, 1844), I observe the particulars of a case of paraplegia which seems not undeserving of a note.

It has occurred to me to find, in the spinal canal, small protrusions of the soft intervertebral substance, somewhat peduncular, and separating the bands of ligament between two vertebral bones. I have felt well assured as to the nature of these little ruptures, and have fairly been in anticipation of one day finding this state to be a cause of paraplegia. The "curious formation" referred to above (p. 212) seems to me, pretty certainly, of the kind I have described. A man, æt. 53, had paraplegia after a strain. There were found, "on the posterior surfaces of the intervertebral cartilages," between the neck and loins, "in two or three places, small, yellow, opaque, friable, bodies, in contact with, and apparently growing from, the intervertebral substance. They did not seem like scrofulous bodies, were very similar to intervertebral substance—a kind of hypertrophy of it, but yellower, firmer, and more brittle. The largest about the size of a pea." These little bodies may attain a certain size, but then I conceive they would only degenerate and waste, being merely old growths, out of place and out of use. They possibly depend on

atrophy, or rupture of the confining ligaments. They shrink sadly when put up as preparations. Perhaps some of your readers may know something more of these bodies; I am not aware that they have been noticed by any writer. My colleague, Mr. John Hilton, who has devoted much time to the study of the spinal marrow, has, I think, seen bodies of the kind referred to.

Your obedient servant,
T. WILKINSON KING.

36, Bedford Square, June 3, 1844.

ON FUNGUS CEREBRI.*

By JOHN ADAMS, Esq.

Surgeon to the London Hospital.

(For the London Medical Gazette.)

I VENTURE to offer a few observations on the pathology of fungus cerebri, to which I attach some importance, and which, if correct, ought to lead to a very considerable modification in its treatment. I entertain a very strong objection to the term "hernia cerebri;" for although the protrusion is usually constituted at the beginning of true cerebral matter, nevertheless, as the disease advances, its character becomes changed, and it assimilates itself to ordinary fungus originating from any highly organised tissue. Where the mass is made up of brain mixed with coagulum, and is covered by the investing membranes, the arachnoid and pia mater, no exception can be taken to the employment of the term "hernia;" but I am confident that the general use of the word has an injurious tendency, as expressive of a false idea of the morbid anatomy of the disease in question, and as, therefore, to a certain extent, justifying a line of practice which is in a vast number of cases highly injurious.

As fungus cerebri cannot occur without the loss of a portion of the walls of the cranium, it is very common to set down the loss of support as a common cause of the disease. But the inference is not necessarily just; for I shall be enabled to prove, by reference to a considerable number of instances, that the exciting cause lies in the brain itself, and that the growth of the fungus depends on some special cause of irritation. The removal of a portion of bone by the trephine will unquestionably

* Read before the Hunterian Society.

bly give rise to a tendency to protrusion of the brain, from the want of due mechanical support, and the afflux of blood to a part thus circumstanced; but, beyond this, it cannot rank as a cause of the disease,—unless it be possible, as some have supposed, and which I do not deny, that the edge of the opening in the bone becomes a source of irritation to the dura mater first, and subsequently to the brain itself.

Of the history and progress of the disease but little need be said; and I am not anxious to occupy the valuable time of the society by any lengthened remarks on this part of the subject. The disease occurs in the following manner. After the loss of a portion of the skull, if the dura mater is intact, this membrane is gradually forced up through the opening, and rises above the bone; it becomes remarkably tense, and takes on a bluish aspect from congestion of its vessels; small dark spots appear here and there, indicative of gangrene; and the gangrene extending, the membrane gives way, and small portions of brain gradually ooze through the openings of the dura mater; and these increasing in size, a protruded mass of cerebral substance fills up the opening. If the dura mater is lacerated at the time of the accident, the fungus makes its appearance with much greater rapidity; but after it has reached the level of the aperture, its progress is the same as in the first case. The shape of the tumor varies; it is in some cases oval, and covered at first by pia mater, which afterwards gives way; in others it resembles a simple vegetation; whilst in others, where it has existed longer, and has been subjected to pressure, it assumes a mushroom-like appearance. In a case mentioned by Mr. Stanley it attained the extent of $6\frac{1}{2}$ inches in one, and $5\frac{1}{2}$ in the other direction.

Of the character of the protruded mass, I may observe, it is brain-like, and is probably at first true cerebral matter, occasionally mixed with large clots of blood; but after a time its character changes, and it resembles to a certain extent ordinary vascular fungus, having still more or less of a cerebriform appearance. Let the finger be carried round the root of the tumor, and it will be found begirt by the dura mater; and the edge of the cranial aperture is frequently found dead.

As to the progress of the disease, I need only remark, that it may proceed in its growth to an almost unlimited extent; that sloughs occasionally occur, and being separated by the efforts of nature, the mass is eventually wholly got rid of, and healthy fleshy granulations appearing, cicatrization takes place; or the disease progresses to the destruction of the patient by exhaustion. A semi-purulent discharge oozes from the general surface of the tumor, and, at intervals, and frequently after an attack of coma, a free discharge of fluid occurs, and the symptoms are for a time relieved.

General symptoms.—After an apparently convalescent state, irritative fever comes on, occasionally succeeded by coma, hemiplegia, and muttering delirium; these are all preceded by great constitutional excitement; and, on the giving way of the dura mater, a remarkable amelioration of the symptoms happens. In other cases, where this membrane has been lacerated, no previous recognizable symptoms usher in the fungus, and the surgeon is much surprised at its appearance without any premonitory signs. The discharge continues to increase, the constitutional irritation is augmented, hectic super-venes, and the patient dies exhausted; or, other vital organs becoming the seat of inflammation, the patient dies from a cause apparently (though not really) unconnected with the original affection,—of which a beautiful illustration occurred recently at the London Hospital.

I shall proceed to point out what I conceive to be the pathology of the disease; and this will necessarily involve some remarks as to its morbid anatomy. To ascertain the true nature of the disease, a superficial, or even a complete, examination of the tumor itself is not always sufficient; this should be extended below the depth of the tumor, and the apparent seat of its connection with the brain; and in many cases there will be found at the root of the tumor, clots of blood, or softening of the subjacent brain, or the brain reduced to a semi-purulent pultaceous mass, or a distinct abscess of greater or less extent; and in the examination a foreign body is occasionally met with, or a spicula of bone is found imbedded in the brain. From the facts revealed to us by dissection,

we are able to arrive more closely at something like a knowledge of its pathology; but it must be apparent that, in most cases, this can only be ascertained after death: nevertheless, it is of the utmost importance that we should have correct notions on a subject of such magnitude. In assigning the removal of bone by the trephine as a common cause of fungus, we should remember that that operation is, in the present day, never undertaken but for the relief of symptoms of pressure or cerebral irritation, and therefore it is not unfair to presume that, in those cases of operation which are followed by fungus, the cause of the disease lies in the brain itself. But it must not be supposed that I deny the loss of bone itself as an occasional cause. Mr. Abernethy attributed the formation of fungus to a confusion of the brain, and the consequent effusion of blood into its substance. From numerous well-authenticated cases, however, it is clear that the disease frequently depends upon either a diseased condition of the brain itself, or the formation of an abscess at the base of the tumor, or some other special cause of irritation, the consequence of injury; for I cannot but rank abscess in this category, although it may be said that the accumulation of fluid in the skull is of itself sufficient to explain mechanically the escape of the cerebral substance.

From the perusal of a few cases to which I shall direct your attention, it will be seen that in the greater number the disease existed at the root of the fungus, and that an altered state of the brain, from suppuration, or some other lesion, must have preceded its formation, and becoming a source of irritation, thus have given rise to its formation; whilst, in others, we cannot fail to recognise a coagulum as its special cause. Mr. Stanley, in his valuable memoir on this subject, in the *Medico-Chirurgical Transactions*, states, in the post-mortem examination of the first case he alludes to: "The exposed surface of the brain from which the portion had been cut off exhibited a softened and broken-down texture, a state of disorganization, which extended deep into its substance: several small effusions of blood were met with between the membranes and in the substance of the brain." In the second case, by the same surgeon, a similar condition of

brain existed at the base of the protruded part, which conveyed the idea of rottenness. In a case also quoted by Mr. Stanley, from Mr. Pearson, "an abscess was found in the anterior lobe of the right hemisphere, containing between two and three ounces of pus. The cavity extended from the anterior part of the corpus striatum to the base of the tumor."

Mr. Abernethy relates a case where the right hemisphere was reduced to a bloody pulp, so as to render it impossible to trace its organization. Mr. Hill also details an interesting case of fungus cerebri, accompanied by abscess, and states, "to prevent repetition of bad symptoms, I was obliged to shave away the tumor, and to push a lancet into its root, as often as the stupor and the symptoms showed that matter was lodged there, by which the patient was uniformly relieved:" the case eventually recovered. Scultetus also mentions a similar case. In the *Lond. Med. Journ.* vol. x., p. 277, two cases are given, in which repeated attempts were made to prevent the growth of the tumor, by pressure: both terminated unsuccessfully, one at the end of a month, and the other at the end of six months. In both cases there was a large cavity filled by a fluid, which had been formed by the accumulation of a fluid that could not escape on account of the aperture being closed by the fungus.

In the *Lond. Med. and Surg. Journ.* for 1831, a case is related by Dr. Tuthill, of fungus cerebri, succeeding a depressed compound fracture of the left parietal bone; the trephine was applied, and splinters of bone were removed from the brain. After a violent attack of inflammation, fungus made its appearance. It was excised by ligature, but it was reproduced. After the loss of a large quantity of cerebral substance, compression of the tumor was employed, which immediately produced paralysis of the opposite side of the body; this continued until the pressure was remitted. He became afterwards violently convulsed, and died about three weeks from the attack. On opening the skull, the brain on the injured side was softened, and infiltrated with pus, and an enormous abscess was found occupying the whole middle lobe, communicating with the ventricle, which was also filled with pus. In the

Journal de Médecine, a case is given, in which, beneath the hernia cerebri was contained a large oblong cavity of eight inches in extent, filled with a greenish pus. In a case which occurred some years since at the London Hospital, at the root of the fungus was an enormous abscess. In two recent cases, occurring under my own observation at the same institution, an abscess is found at the root of the fungus.

Not to multiply evidence on this subject, and without quoting the cases of fungus as the result of foreign bodies in the brain, as given by Mr. Mallett, in the Transactions of the Prov. Med. and Surg. Association, I think I have stated sufficient to prove that fungus is not always a disease depending so much upon the want of due support to the brain, but frequently on some special cause of irritation, as fungus is produced in other organized tissues. But what, it may be asked, is the inference from these facts? It amounts, in my opinion, to this, viz. that with such facts before our eyes, the persistence in an indiscriminate employment of compression in fungus cerebri cannot be justified, and that a prudent surgeon should weigh well all the symptoms of the case, before he makes up his mind to continue the use of pressure, if the case is proceeding, as is not uncommon, from bad to worse. But it may be asked, are there any symptoms by which we can distinguish this form of the disease from that of a simple character? I confess I have but little satisfactory to offer on this subject; but I must remark, that in the very last case which came under my observation, I ventured to predict the existence of abscess, from the occasional rigors which attacked the patient, and from the occasional escape of a large quantity of matter. (I may state that this patient died of pleuritic effusion and purulent depôts, so common in cases of suppuration at a part remote from the seat of the fatal attack.) If the idea of suppuration at the root of the fungus, should, from symptoms but slightly referred to, enter into our minds, and if our patient be suffering from the effects of the disease, what plan of treatment can be suggested? To this I would answer, that the cranial aperture should be enlarged, as has been suggested by Velpeau, and as is justified by the experiments of Flou-

rens, that the root of the tumor should be explored by the grooved needle, and the propriety of at once laying open the abscess would readily be recognized. I confess I offer this suggestion with some diffidence, as it implies a degree of hazard which may seem presumptuous, but the success of the case mentioned by Mr. Hill appears in my mind to establish a precedent for a plan of treatment which certainly only the urgency of the symptoms can justify. I may mention one advantage likely to result from the use of the grooved needle, namely, the detection of a foreign body, as a spicula of bone, &c., the removal of which may at once arrest the further growth of the tumor.

31, New Broad Street, May 1844.

DIGITALIS IN MANIA.

To the Editor of the Medical Gazette.

SIR,

You were so kind as to publish, in the Number of your excellent periodical for last December, two cases of epilepsy complicated with mania, or maniacal delirium, corroborative, as I conceive, of an opinion stated in my work*, viz. that both analogy and some established facts go far to shew that digitalis, in large doses, exerts a very decided control over the latter as well as the former disease. Since then, having had an opportunity of making a further trial of the practice, and feeling that the subject is an interesting one, I beg now to submit the results. I would observe that the case of epilepsy was not one of the class which I consider curable by the "heroic" dose; and in giving the doses which I did, I had no expectation of curing the disease, but merely of moderating the attacks, and perhaps preventing their so frequent occurrence.—I remain,

Your obedient servant,

EDMUND SHARKEY, M.D.

1, Winchester Place, Jersey,
May 11th, 1844.

CASE I.—Thomas Meddar, æt. 50, formerly addicted to drink, but for the two last years temperate; has suffered severe reverses of fortune, and has subsequently been subject to fits of

* "Inquiry into the Efficacy of Digitalis in Idiopathic Epilepsy."

maniacal excitement accompanied by severe head-ache.

He came under my care on the 9th of June, 1844, when he was in the following state. He had severe pain of the head, described as a darting pain, principally confined to the left temporal and parietal regions; his brow is knitted, and the expression of his eye stern; he has been freely purged for two days past, without any benefit. Being informed that, on similar occasions, he had been bled with advantage, I drew about a pint of blood, producing syncope. I applied a blister to his neck, and gave him Calomel and James's Powder, aa. gr. j. three times a day.

10th.—Blood drawn not indicative of inflammation; he spent, however, a better night; bowels confined.

Sumat. Infus. Sen. c. Antim. ad Eff.

Blister to be dressed with Ung. Sabinæ.

12th.—Bowels open; inclined to be violent last night; complained much of pain of head, and does so still.

Sumat. h. s. Tr. Digital. ʒj.

13th.—A quiet night, but headache continues.

15th.—Is incoherent; talks and sings, but is not violent; blister discharges copiously; ptialism; pulse 92, and soft.

16th.—Slept, and is rational; pulse 88.

Tartar Emetic Ointment to be rubbed on the neck.

23d.—Bowels regular; pulse as before; he has been in general quiet, but occasionally incoherent, and has complained much of his head; ptialism continues.

Sumat. Extr. Belladon. gr. ss.; P. Jacobi, gr. j. ter in die.

Feb. 9th.—No important change since last report till last night, when he was very violent; he still continues very incoherent; bowels confined.

Sumat. statim Haust. ex Tinct. Digital. ʒj.; Mist. Camph. ʒj. Necton Mist. Purgat.

10th.—Has been quite tranquil, and slept.

Rep. Haust. Tr. Digit. si opus.

12th.—Has been violent, and has taken the draught, but without the effect of producing sleep.

R. Tr. Digital. ʒss.; M. Camphoræ, ʒjss.; M. sumat. Cochl. ij. ampla p. r. n.

14th.—Having been anxious and troublesome on the previous night, he yesterday took a dose of the digitalis mixture, which immediately tranquillized him, and he has slept almost ever since. Pulse 45.

15th.—Became again violent last night, complaining much of his head, but did not get a dose of the mixture. Bowels confined; pulse 52, intermitting. Headache severe; appetite keen.

19th.—Quiet since; head better; pulse 46; postular eruption on neck.

24th.—Still tranquil, and head much better; pulse 60.

March 6th.—Continues to improve; pulse 52, full, but intermittent.

7th.—Violent again last night; pulse 72; bowels confined.

13th.—Continues tolerably well; the pulse still presents decided intermission.

April 11th.—Still tranquil; head occasionally complained of; pulse has become normal in number and rhythm; bowels generally confined; is able to take exercise in the open air, to which, however, he is much disinclined; and he would, if allowed, remain constantly in bed. He is, on the whole, much improved.

In this case, where, from the obstinate persistence of severe local pain, in spite of active treatment, there is some ground for suspecting organic change within the head, we have seen very marked benefit derived from large doses of Tinct. Digitalis; and in a case which admitted only of palliation, it is no small satisfaction to have succeeded, as I certainly did several times, in reducing him from a state of violence dangerous to the safety of those about him, into one of perfect tranquillity, without the necessity of employing any restraint. It may be important to mention, that there is, in his family, a tendency to this form of disease.

CASE II.—The next case is brought forward for the purpose of shewing that the peculiar state of the nervous system which exists in epilepsy seems to confer a tolerance of this powerful sedative which we should have little anticipated. It is one in which the digitalis was more freely given than in the former, though it was characterized by a remarkable weakness and irregularity of the pulse, which was of unequal strength in the two arms, being sometimes scarcely distinguishable the right. It

Rep. Haust. Tr. Digit. si opus.

12th.—*Has been violent, and has taken the draught, but without the effect of producing sleep.*

℞ Tr. Digital. ʒss.; M. Camphoræ, ʒjss.; M. sumat. Coch. ij. ampla p. r. n.

14th.—Having been sleepless and troublesome on the previous night, he yesterday took a dose of the digitalis mixture, which immediately tranquilized him, and he has slept almost ever since. Pulse 48.

15th.—Became again violent last night, complaining much of his head, but did not get a dose of the mixture. Bowels confined; pulse 52, intermitting; headache severe; appetite keen.

19th.—Quiet since; head better; pulse 48; pustular eruption on neck.

24th.—Still tranquil, and head much better; pulse 60.

March 6th.—Continues to improve; pulse 52, full, but intermittent.

7th.—Violent again last night; pulse 72; bowels confined.

13th.—Continues tolerably well; the pulse still presents decided intermission.

April 11th.—Still tranquil; head occasionally complained of; pulse has become normal in number and rhythm; bowels generally confined; is able to take exercise in the open air, to which, however, he is much disinclined; and he would, if allowed, remain constantly in bed. He is, on the whole, much improved.

In this case, where, from the obstinate persistence of severe local pain, in spite of active treatment, there is some ground for suspecting organic change within the head, we have seen very marked benefit derived from large doses of Tinct. Digitalis; and in a case which admitted only of palliation, it is no small satisfaction to have succeeded, as I certainly did several times, in reducing him from a state of violence dangerous to the safety of those about him, into one of perfect tranquillity, without the necessity of employing any restraint. It may be important to mention, that there is, in his family, a tendency to this form of disease.

CASE II.—The next case is brought forward for the purpose of shewing that the peculiar state of the nervous system which exists in epilepsy seems to confer a tolerance of this powerful sedative which we should have little anticipated. It is one in which the digitalis was more freely given than in the former, though it was characterized by a remarkable weakness and irregularity of the pulse, which was of unequal strength in the two arms, being sometimes scarcely distinguishable in the right. It was that of a widow, aged

29; the mother of four children. She states that she became epileptic at the age of 9 or 10, in consequence of a fright, but was cured in about a year after the first invasion. She states that, eleven years ago, grief brought on a return of the disease, by which she has been ever since afflicted, especially at her menstrual periods. Her general health is good. Instead of the fully formed paroxysm, she sometimes gets fits of temporary fatuity. She was treated, in the first instance, with purgatives, large doses of Sulph. Zinci, Nitr. Argenti, Sulph. Quin., Turpentine, and Ammoniacum of Copper, without much benefit; she took, subsequently, Tinct. Digitalis in large doses, the general effects of which it is now my chief object to detail.

The first dose (3ij.) was given on the 27th of last September: the report on the 28th was as follows. Has not vomited, but is weak and vertiginous; pulse 80, *not more irregular than before*.

Oct. 1st.—Pulse 52—54.

12th.—A fit last night; pulse 100, not intermittent.

Sumat Tinct. Digital. 3ij.

14th.—A fit; has been for some time subject to vomiting of a fluid like coffee-grounds.

Nov. 1st.—Was yesterday fatuous, and a similar draught of the tincture was given, after which she *slept well*. Is up to-day, and feels quite well, and has improved in look. Pulse 72, with marked intermission.

20th.—Had a fit on the 17th; coffee-grounds vomiting continues; pulse 56, regular.

Dec. 11th.—Is now taking Ol. Terebinth, 3j. ter in die. Vomiting has ceased.

Jan. 27th.—Is fatuous.

Sumat. Tinc. Digital. 3j.

On the 9th and 10th Feb. had fits, followed by costive bowels, quick pulse, and heat of skin. On the 10th took a draught with—

Ol. Tereb. Ol. Ric. aa 3j., followed at bed-time by Tinct. Digital. 3ij.

Bowels were freely opened, and she *slept better* than for three previous nights, which had been nearly sleepless; countenance improved; and pulse 62, but slightly irregular.

On 13th another fit. Draught of Tinc. Digit. was repeated.

14th.—Slept, and is well to-day.

17th.—Took Tinc. Digit. 3ij.

20th.—Repet. Tinc. Digit. 3ij.

23d.—Pulse intermittent; stomach irritable; head giddy.

24th.—Pulse 64, very intermittent.

March 16th.—A slight fit; took, after it, Tinc. Digit. 3ij.

18th.—Pulse 52.

19th.—A fit; face swollen and red; tongue white; pulse 100.

Sumat. Tinc. Digital. 3ij.

20th.—A good night's rest; is less stupid; pulse 64, intermittent.

22d.—Vertigo; pulse highly intermittent.

25th.—Pulse 48, more intermittent; vertigo increased.

It would be useless to pursue this case further, as the fits still occur; but I think I have sufficiently shewn how freely digitalis may be administered, not only without injury, but with positive benefit, in allaying nervous excitement and procuring sound sleep, where opiates appeared inadmissible. For other cases of these diseases thus treated, and further information on the free use of this remedy, I beg to refer to Case 9 of my work; also to Dr. Hallaran's and Mr. Knight's *Treatises on Insanity*; also to Pereira's *Materia Medica*, art. "Digitalis."

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

On Dysmenorrhœa, and other Uterine Affections, in connection with Derangement of the Assimilating Functions. By EDWARD RIGBY, M.D. &c. &c. Pp. xii. and 140. Renshaw. 1844.

THIS work is avowedly a superstructure upon that "On Stomach and Urinary Diseases," by Dr. Prout; of whose views on the influence of an excess or mal-assimilation of the albuminous and gelatinous principles in the production of the lithic, rheumatic, and gouty diatheses, the author is a thorough-going partizan, and to the existence of which he is disposed to attribute nearly all the maladies that assail us from infancy to age—grinding of the teeth, clenching of the hands, mollities ossium, tabes mesenterica, and other glandular diseases of the scrofulous

constitution, phthisis pulmonalis, and organic diseases generally,—all are owing to an acid state of the fluids, produced by an imperfectly assimilated chyle, or its conversion into the comparatively insoluble pseudo-albuminous matter of struma, arrested in some part of the circulation, instead of being thrown out by the kidney and other emunctories of the body.

One really feels at a loss how to take down matter of this description at the present day. Have we fallen back upon the times of Paracelsus and Van Helmont? or has Dr. Rigby caught a Tartar in these chemical theories of disease? Is he, instead of leading, himself led, and that into a maze or quagmire where he is engulfed and lost? We cannot tell; but seriously opine, that Sir Topas must be brought to Malvolio tricked out in yellow stockings, and cross gartered—in garments that do not belong to him. But “*revenons à nos moutons.*”

The book consists of two parts. The first discusses Assimilation and its derangements; the second is entitled Uterine Affections. Seven cases follow, along with three of which tabular analyses of the urine are given; and the whole concludes with “a few simple directions, by which a practitioner, without much previous knowledge of the subject, may soon learn to observe and appreciate the more important phenomena which the urine presents in the diseases to which I have been alluding.” The first part is merely introductory to the second, where the reader is informed that Dr. Rigby’s object is not to point out new remedies for the treatment, but to illustrate the connection which exists between the rheumatic and gouty diatheses and certain uterine affections; and likewise to call attention to the circumstance that the local symptoms are little more than part of a general diathesis, without an effectual impression upon which but little relief can be expected.

When mal-assimilation, particularly of the albuminous and gelatinous principles, attempts to localize itself on the uterine system, Dr. Rigby proposes, in default of a better term, to call it “rheumatic gouty affection of the uterus.” The symptoms of this *new* disease enumerated are those of—will the reader believe it?—*dyspepsia in general*! God help the poor stomach! it

has a deal to answer for in these days!—*dyspepsia* in general, attended with a more or less marked state of congestion of one or other of the pelvic viscera at the menstrual periods, or the half-way times between them. This congestion is described as at first transitory, but soon acquiring a more permanent character, until at length a state of subacute or chronic inflammation is established, which terminates in structural mischief.—For a full and particular account of the fashionable hypothesis involved in which assumption, vide Dr. Wilson Philip’s book “On the Tendency of certain Derangements of the Digestive Function to end in Organic Disease of the Instrument by which it is performed.” In many instances the disease seems chiefly confined to the vagina and rectum, producing atonic leucorrhœa, or hæmorrhoidal congestion, without the uterus appearing to suffer much during the menstrual periods; but in other and more acute forms, dysmenorrhœa, usually accompanied with fibrinous exudation, is present, especially where the general diathesis has been led to fasten itself upon, or to show itself in, the uterine system, by exposure to cold during a menstrual period, or by an abortion at an early date. Dr. Rigby says that he is unable to state with certainty the precise circumstance on which the formation and discharge of fibrinous exudations depend. “Neither the severity of the attack, nor the peculiar type of the accompanying symptoms, nor the habit of the individual herself, seems to stand in any relation or connection with the appearance of these discharges of fibrinous matter. If there be any fact which seems to be common to all the cases of dysmenorrhœa which have been attended with exudation, it is the co-existence of some local inflammatory action in a neighbouring organ. In some it has been the kidney; in others (and, on the whole, more frequently) the ovary: which may easily be presumed, from its close connection with the uterus, and from the generally-received opinion of its being essential to the function of menstruation. In others the os and cervix of the uterus have been the seat of inflammation.”

Now all this appears to us, to say the least of it, grossly inconsistent with the announcements put forth in our author’s

title-page, and reiterated in his preface. Occasional connection between dysmenorrhœa and rheumatic affection, and its treatment by means of guaiacum, colchicum, and the like remedies, were long ago dwelt upon by Dr. Locock, in the Cyclopædia of Practical Medicine. Our author's adoption of that view, with the additional idea that rheumatism played a more important part in uterine pathology than was generally imagined, was proclaimed in his Treatise on Midwifery. Surely Dr. Rigby is not prepared to contend that he has added to the common stock of knowledge, and proved the frequent concomitance of uterine affection and rheumatism, by publishing seven cases of their simultaneous occurrence! We engage to supply him with twice as many from our note-book, where nothing of the kind could either be traced or suspected. We are, indeed, at a loss to conceive any legitimate professional object for which this work could have been produced. It seems a mere excrescence from, a parasite upon, the dazzling chemo-pathological speculations of the modern chemical pathologists, especially of Dr. Prout and Liebig—we cannot dine without finding Liebig in our dish now!—and the practical application by Dr. Todd of the modern and fashionable version of the humoral pathology to the explanation of the erratic phenomena observed in gout and rheumatism.

We are sorry to find the whole of Dr. Rigby's publication written in a style and manner so much below the level of the general acquirements of the profession, that it is only adapted to convey information to the frequenters of the outer court of the temple of science. We have even grave misgivings of the book having been written for the profession at all; a suspicion which, did it acquire shape, we should make the ground of a severe visitation upon Dr. Rigby, especially in connection with such a subject. Books upon female complaints ought to be sacred to professional eyes, and written up to so high a mark that no other than professional readers could peruse them with understanding. There is nothing, in our mind, between Aristotle's Masterpiece and the most serious inquiry into the mysteries of generation and its accompanying phenomena, as matter of the deepest philosophical import.

Contributions to the Diagnosis of Emphysema. By R. L. MACDONNELL, M.R.C.S.I. &c. &c.

THE subject of empyema has lately had a large share of notice in our pages, as our readers are aware; first, in our abstracts of Dr. H. Roe and Dr. T. Thompson's papers on Paracentesis Thoracis, read at the Medical and Chirurgical Society, and of the interesting discussion that followed; and, second, in our analysis of the last published Part of the Guy's Hospital Reports. To put our readers *au niveau* on this important subject, we feel bound to refer them back to the March number of the Dublin Journal of Medical Science, where they will find a great deal of new and most interesting information on certain rare forms of empyema; forms, to wit, in which the matter made its way to the surface in the vicinity of the heart, and in the guise of *pulsating tumors* that simulated aneurism in a very remarkable manner. Two original cases of this kind are given, and a third is quoted. The writer makes some very pertinent remarks upon the purulent expectoration that frequently occurs along with empyema. In his first case, for instance, the patient in the course of one day expectorated a whole pint of greenish pus, at which time the diarrhœa under which she laboured received a notable check; but the post-mortem examination showed the bronchial membrane in a perfectly healthy condition; and no trace of communication between the sac of the empyema and a bronchial tube could be discovered. There were tubercles in the lungs, indeed, but these were all in a crude and unsoftened state. The author is inclined to view the discharge of pus by the bronchial membrane and bowels, in such cases, as vicarious of the purulent secretion into the pleural sac. "An evacuation of pus, by absorption, secretion, or some other process, is effected, which is attended with a diminution in the empyema."

The author has further some excellent observations on the "condition of the sound lung in empyema," which is somewhat liable to be affected with proper bronchitis, for which no satisfactory cause can be assigned save the additional duty that is imposed on it in consequence of the useless state of the other lungs. We are not, however, to

be over solicitous about the *mere physical signs of bronchitis* unaccompanied by general symptoms—a certain and often unavoidable degree of congestion that is not dangerous in itself, will cause these physical signs; a little attention, however, enables us to distinguish this state from acute bronchitis or pneumonia.

We find still further, in perusing this important paper of Mr. MacDonnell, some very curious and original remarks on the condition of the liver in empyema. It is generally held that the only way in which this great viscus is implicated in empyema is by being mechanically depressed when the purulent collection is in the right side of the thorax. Mr. MacDonnell has shown that the same enlargement or depression of the liver often occurs equally when the effusion is on the left, and that it is due in fact to a congested state of the organ, similar to that which occurs along with morbus cordis and diseases of the lungs attended with imperfect aeration of the blood. On the whole, we regard this contribution of Mr. MacDonnell to the pathology of empyema as one of the most original of any that have ever been made on that important and dangerous disease.

MEDICAL GAZETTE.

Friday, June 7, 1844.

“*Licet omnibus, licet etiam mihi, dignitatem Artis Medice tue; potestas modo veniendi in publicum sit, dicendi periculum non recuso.*”

CICERO.

EXCESSIVE DIVISION OF LABOUR IN THE PRACTICE OF MEDICINE.

WE are very much disposed ourselves to view the healing art as one and indivisible. We have no doubt as to the propriety of there being but one course of study for all who devote themselves to the medical profession. Having gone through this, it would afterwards be competent for each man to choose the walk for which he felt inclination or natural aptitude. He would practise medicine, or surgery, or midwifery, did he chance to settle himself either in a large town or in a populous coun-

try; did his stars cast him on a village, or a more thinly-peopled district, or did he seek refuge in the army or the navy, he must hold himself armed at every point—ready to trepan a skull or take off an arm, to treat an ague and to help a woman in her confinement, as the case might be; and such is the close connection between all the parts of medical science, that he who has been well grounded, and devotes himself zealously to his profession, may perform each and all of these offices with perfect propriety, and even advantage to the patient. We have seen our army and navy surgeons, when cast loose by peace, or disgusted with service, settling themselves indifferently as pure physicians, as pure surgeons, as accoucheurs, and in still larger numbers betaking themselves to general practice, and acquiring a reputation in each and all of the three grand divisions of the profession.

In large cities and populous neighbourhoods, we are nevertheless favourable to a division of labour to the extent of physic, surgery, and obstetrics; but it is obvious that, conceding so much, we run great risk of being required to give more: a certain amount of division of labour, it is said, is allowed to be good; a greater amount of subdivision must be still better. This we believe to be a grievous and most pernicious error; but it is one that is spreading, and that under the countenance of interested individuals; and, from the gross ignorance of the public upon matters medical, is likely to extend still farther. We have no longer physicians, surgeons, accoucheurs, but we have physic split into various sections, and have mad-doctors, lung-doctors, stomach-doctors, skin-doctors, &c. Surgeons, again, we find in such divisions as lithotomists, oculists, aurists, orthopedists, &c. Obstetricians preserve their integrity as yet; but there will probably be a split among

them by and by, if the prevailing taste continue.

Our forefathers instituted general hospitals for the relief of the sick of all kinds and denominations; they did not imagine that because a man's eyes were the part of his body which was suffering, any other than the attendant in ordinary was required to set them right;—they never dreamt of ophthalmic surgeons, any more than they thought of ophthalmic hospitals. Mr. Cheselden was the most distinguished surgeon of his day, and cut for the stone, and couched for the cataract, and did every thing that an accomplished surgeon could be asked to do, and should be ready to do. In the present day, we see the profession cut up into shreds and patches,—we think with very questionable benefit to the progress of true medical science, or to the public. The most ignorant and conceited men we encounter in the profession are those who limit their practice to a particular subject or branch; and it is quite certain that these are never the men who push forward the car of science; on the contrary, they are generally the last to yield to improvement.

It is wonderful, however, to what an extent the public may be won by taking them on a crotchet or a whim; and how much they are disposed to listen to nostrum-venders and curers of particular maladies and infirmities. The more ignorant the man, too, the more is he fitted to succeed on this tack: "What a very ignorant man Mr. ——— is," said a lady friend of ours one day, speaking to us of her professional attendant in ordinary; "I do not know that I ever met with so ill informed a man; but I suppose he knows his profession all the better for that." This is the secret. The world see a man doing impossibilities upon the fiddle, or the flute, or the bassoon; or they see a juggler bringing the whole

of Covent Garden from a crownless hat; and straightway the world judge of us as medical men by the standard of fiddlers and mountebanks: if we are informed beyond the pale of our profession, we cannot have given our undivided attention to that: we can do something more than balance a straw upon our nose, and then we are mistrusted; if we have no accomplishment on earth,—if we are as ignorant as Mr. ———, — we are straightway esteemed to be very Solomons on the one thing needful, and taken into the heart's most intimate confidence.

We were led into some part of the preceding reflections by having a letter put into our hands yesterday, headed "Testimonial to Mr. Frederick Salmon." On going further we found these words:—

"Sir,—I have the pleasure of forwarding you, at the request of Capt. Sir Edward Parry, (Chairman of the Provisional Committee), the annexed copy of a requisition to the Right Honourable the Lord Mayor, by which you will perceive his Lordship has appointed One o'Clock on Saturday, the 8th of June, for the Meeting, at the Hall of Commerce, Threadneedle Street, when the Committee *urgently* solicit the honour of your attendance.

"Major General Sir James Law Lushington, K.C.B. has intimated his intention of taking the Chair at Half-past One o'Clock *precisely*.

"I have the honour to be, sir,

"Your obedient servant,

"THOMAS HOWELL, Jun.

"Honorary Secretary, *pro tem*."

Still farther, we find a formal requisition to the Rt. Hon. Wm. Magnay, Lord Mayor of the City of London, requesting him as "President to the Infirmary for Fistula and other Diseases of the Rectum, to convene a special meeting for the purpose of taking into consideration the most suitable means of testifying the high sense entertained of the manner in which Mr. Frederick Salmon, the Founder and Surgeon of the Charity, has gratuitously performed the arduous and responsible

duties of his office, and to mark the estimation in which his private worth and the services he has rendered to science (!!!) is held." The whole signed by hard upon two hundred names of respectable gentlemen—and, will it be believed? by no fewer than twelve gentlewomen. Think of twelve English women requesting the Lord Mayor of the City of London to convene a meeting for the purpose of testifying their high sense of Mr. Frederick Salmon's merits as the founder and surgeon to the "Infirmary for the Relief of Fistula and other Diseases of the *Rectum*!!!" There are some among the gentlemen subscribers, too, from whom we should have augured and expected better things than that they should appear lending themselves to any quackery or nastiness. What have Capt. Sir Edward Parry, or Charles Dickens, or Thomas Bell, F.R.S. to do here? If Dickens means to get a character or so for his next new work from the Governors, male and female, of the "Infirmary for the Relief of Fistula and other Diseases of the *Rectum*," or if he is studying the interesting traits in the features and feats of the founder, we will excuse him; if not, if he have no such purpose, we recommend him, with his brother governors and governesses, to find out some one who will "cut him for the simples," as well as for fistula or the piles.

But seriously this is a great evil, and makes all honest and plain medical men blush for the profession to which they belong. There is something disgusting, and in the last degree indelicate, in making parade of such matters of privacy as diseases of the *rectum*.

The subject has long been known to be a popular one, however, and any man with sufficient bluntness of the finer senses to take it up was pretty sure of finding it answer his purpose. There was an old apothecary at Bath who had a very large practice in this

line, and whose room used to be seen set round with patients *impaled in a small way*! We shall not venture on the trisyllable which we once heard Sir E. Home use in connection with this old apothecary's practice, or on the disyllable which he applied to those who subjected themselves to it—faugh! we are so disgusted with the panorama of indelicacy and imbecility which this requisition brings up before our eyes, that we fly from it, and the actors in it, with loathing.

REWARD OF SCIENTIFIC MEN IN THIS COUNTRY.

We honour Sir Robert Peel for the handsome way in which he spoke of men of science generally, whilst alluding particularly to the most distinguished comparative anatomist and palæontologist of our country, or of Europe—Mr. Owen. Whatever salary Mr. Owen had from the College of Surgeons, he was still worthy of consideration by the Minister with a fund at his disposal for the reward of literary and scientific desert. When we see by the statement, which we presume must have been furnished by the College of Surgeons, that Mr. Owen's emoluments from his office—and much arduous duty he does for the money—do not exceed £550 per annum, we see that the Premier did well and wisely in awarding Mr. Owen an additional £200 per annum for his life. Had Mr. Owen been born in France, instead of England, and laboured as he has done, he would himself have been minister of the crown, and filled a place of honour and emolument that would have made him independent of any such consideration as he has been fortunate enough to receive. But being born in England, he is nobody, save in his privacy, and had he "bestowed his talents on a distillery," he would have made more money than ever he will make by science.

ROYAL MEDICAL & CHIRURGICAL SOCIETY.

Tuesday, June 8th, 1844.

THE PRESIDENT IN THE CHAIR.

Case of Dissecting Aneurism of the Aorta, Innominata, and Right Carotid Arteries, causing suppression of urine, and white softening of the right hemisphere of the brain. By R. B. TODD, M.D. F.R.S. &c.

THE patient, a stout plethoric man, æt. 37, was suddenly seized, while dining at a friend's house, at Norwood, in Surrey, with syncope, from which he soon recovered. He was taken to the house of another friend in the neighbourhood, and Mr. Street attended him. His symptoms at this time were, violent pain in the loins, down the course of the ureters, thighs, and abdomen, with some tympany and swelling of that region, nausea, and scanty urine. Notwithstanding depletion, local and general, purging and diuretics, the kidneys ceased to act, and other signs shewed themselves. He became paralytic of the left side; the pulse of the right side was distinctly smaller and weaker than that of the left: there was bellows sound in the course of the aorta and innominata, and the breathing in the right lung was less audible than that of the left. There was also great drowsiness and sluggishness, indicating oppressed brain.

About the fifth or sixth day the secretion of urine returned, but the cerebral symptoms shewed but trifling signs of amendment. The pupils, which had before been unequal, became equal, and some power returned to the paralysed side; but the pulse began to falter, and signs of an internal hæmorrhage manifested themselves, and on the eleventh day from his seizure he expired quite suddenly.

A copious effusion of blood was found in the pericardium; this had escaped through a little fissure in the outer coat of the aorta, which formed the external ovule of a recently formed aneurismal sac. This sac communicated with the aorta through a transverse rent in its inner and middle coats, which originated in an ulcerated atheromatous spot. The blood which thus escaped from the artery made a new channel for itself along the aorta, and also along the innominata and right carotid arteries, by splitting the middle tunic of those vessels into two laminæ. The separation took place in the carotid at some distance up the artery, and was then stopped, the consequence of which was the plugging up of that artery, and the cessation of the circulation in it.

The right hemisphere of the brain was exsanguineous, and all that part of it which is above the fissure of Sylvius (which is supplied with blood by the middle cerebral artery) exhibited numerous patches of

softening, without discolouration, affecting the white matter, as well as the grey substance, of many of the convolutions. This softening Dr. Todd attributed to the stoppage of the circulation in the right carotid artery, the vertebral not being able to render its full share of blood, owing to the diminished calibre of the innominata and subclavian. The kidneys were in the second stage of granular disease. The temporary cessation of the action of these organs was doubtless due to a temporary impediment to the full flow of blood to them. The paralysis and the somnolency were clearly to be attributed to the physical alteration in the right hemisphere of the brain.

The case was attended by Mr. Street, of Norwood, and by Dr. Todd, and was seen once by Dr. Watson.

Dr. Williams commenced the discussion by inquiring whether the region of the back had been auscultated, as he should have expected any murmur that existed to have been heard loudest in that situation.

Dr. Todd, in reply, stated that he had done so, but found no audible murmur in that situation.

Mr. Solly inquired whether the contracted state of the right pupil, which had been observed in the commencement, continued unchanged till the death of the patient.

The Secretary reread a portion of the paper, to show that the state of the pupils by and by became uniform.

Mr. Phillips had witnessed three cases of dissecting aneurism of the aorta, but they had occurred at a more advanced period of life than the one just related to the society. The patients were all between 60 and 70. He detailed one in a bed-ridden female.

He dissented from the explanation of Dr. Todd, that the state of the brain was produced by the obstruction to the cerebral circulation, inasmuch as pathologists were not generally agreed whether softening was the result of stoppage of the circulation or of some inflammatory process. The state of the kidneys might account for the cerebral symptoms.

Dr. Williams observed on the much greater size which aneurisms possessed during life, when they were distended by the force of the heart, than would be imagined from the state of the parts inspected after death. This was of importance in estimating the size of aneurismal tumors during life, by the aid of auscultation and percussion. He alluded chiefly to thoracic aneurisms, but had observed the same circumstance in abdominal aneurisms. He detailed a case where the sign usually furnished by the state of the pulse was wanting, but in which the anomaly was explained, after death, by a portion of the coats of the

vessel having become implicated, so as to form a valve of the artery, and thereby annihilate the circulation through it. He thought the explanation of the head symptoms advanced by Dr. Todd essentially correct, and dissented from that of Mr. Phillips, inasmuch as ischuria was attended with symptoms of general oppression of the brain, and not with those of paralysis.

Mr. Snow observed that the unnatural channel mentioned in the descending aorta might have terminated a pouch, and hence there would be no circulation through it, and no sound heard in the back. Dr. Todd considered this view as very probable; but as the aorta had been divided before the termination of the new channel had been completely traced, he could not positively affirm that it ended in a shut sac, although it very probably did so.

The President, in reference to the important influence of the circulation in the carotid over the functions of the brain, alluded to a case in which Mr. Vincent tied that vessel: the man was immediately seized with paralysis. In Mr. Abernethy's first case of ligature of the common carotid, inflammation (qy. softening) of one of the cerebral hemispheres was likewise found.

Mr. Lloyd's experience led him to consider softening of the brain as the product of inflammation rather than of interruption to the circulation, and in this he thought he was supported by the treatment which he had found most successful—local depletion, with general stimulants and nutritious diet.

Mr. Lloyd again rose, and, in commenting on the practice of depletion, observed that in his younger days a patient was seized with symptoms of paralysis, for which he bled to some extent. The paralytic symptoms increased, and he was greatly blamed by the very practitioners who, at a subsequent stage, employed still larger depletion, with a successful termination of the case.

Dr. Willis remarked on the interesting nature of the case, and the perfectly satisfactory manner in which, in his opinion, all the symptoms were accounted for by the post-mortem appearances. He related a case which illustrated the influence of defective circulation on the cerebral functions in a very remarkable way. A lady was considered as being what was called nervous; she spoke little, was out of spirits, shunned the light, and ceased to take interest in her needlework, &c. The hesitation in this patient's speech, and the general symptoms, led him to look more seriously at its probable issue than had yet been done, and to diagnose incipient organic disease of the brain. No kind of treatment did any good. On visiting the patient one morning, about four miles from town, he found the face drawn to the right side. There was little

pulse, but he thought it fair to try the effect of a cautious bleeding; the arm was tied up, and a small orifice made in the vein; before four ounces had flowed, the left arm fell, upon which the further loss of blood was immediately arrested. Matters went on from bad to worse; the patient became completely hemiplegic, and about six weeks afterwards she was seized with convulsions on the right side, and died comatose. On opening the head nearly the whole of the middle lobe of the brain on the right side was found pulpy and soft, of a yellow colour in the middle of the softened mass, of a dirty white in the rest; and the middle artery of the brain, which nourished this hemisphere, just where it passed up over the front of the corpus callosum, was found obstructed by a firm coagulum, evidently of old formation. To the formation of the obstruction in this vessel he felt disposed to ascribe the whole of the mischief which had occurred in the case.

Dr. Mayo approved the practice which Dr. Willis had followed; it was judicious, it was cautiously undertaken; and unquestionably the fatal result had had nothing to do with it. He was of opinion, however, that in all probability a clot had existed in the softened portion of brain as the first step in the mischief, and that the coagulum found plugging the vessel was an after-effect. Softening of the brain almost always began around clots of effused blood.

Dr. Kingston thought, from the care and industry with which Dr. Abercrombie had collected materials for elucidating the pathology of softening of the brain, we were bound to adopt his conclusion that the white softening unattended with discolouration depended on some interruption to the circulation of that part.

A Case of Scirrhus of the Thyroid Gland.

By R. W. BROWN, Esq., Surgeon to the Bath United Hospital. [Communicated by Sir B. C. Brodie, Bart.]

THIS case was considered by the author to be interesting in connection with the paper communicated to the Society by Mr. Caesar Hawkins, on Carcinoma of the Thyroid Gland. The patient, aged 60, began, about Christmas 1842, to have pain in the larynx, accompanied by hoarseness; and his voice gradually became feeble and stridulous, so that he could scarcely speak above a whisper. A hard swelling soon presented itself in the situation of the left lobe of the thyroid gland, and which could be traced in the direction of the oesophagus. The integument in this part of the neck became thickly studded with hard tubercles of a cancerous character. The patient at length had great difficulty of swallowing, which increased, and he died, after much suffering, in June

1843. On the post-mortem examination, the left lobe of the thyroid gland was found to be the principal seat of disease. It was enlarged, and converted into a mass of carcinomatous substance, white, hard as cartilage, and with some gritty particles dispersed through it. The lymphatic glands on both sides were also converted into the same morbid structure, and compressed the oesophagus. Tumors of the same kind were found in other parts of the body, particularly in the lungs and the liver.

Case of Necrosis of the Lower Jaw recovered from without Deformity. By WILLIAM SHARP, F.R.S. F.G.S. F.R.A.S., Senior Surgeon to the Bradford Infirmary.

THE patient, a female, aged 20, was first seen by the author in the beginning of Sept. 1842, six months after the disease began, with symptoms of necrosis of the lower jaw. He extracted one of the teeth, and found a small fungous growth attached to its fang. On the 13th December, he lay the sinuses communicating between the diseased bone and the skin into one, and slightly enlarged the opening; he then drew out with the forceps the dead portion of the lower jaw, which was found to consist of about two-thirds of the entire bone, and it contained several of the alveolar processes. The author was gratified, on looking into the patient's mouth, to find that, with the exception of the tooth which he had extracted, the whole set of excellent teeth were perfectly fast, and in their proper places. The portion of bone which had been removed was exhibited to the Society.

Mr. Lloyd's experience had informed him that cases of extensive exfoliation of the jaw where the teeth were preserved were not at all uncommon. He had seen many such.

The President owned that he never had seen any case of the kind.

Before adjourning the Society, he informed them that Mr. Snow wished to exhibit, and was ready to explain to the members, an instrument which he had invented for the removal of fluid from the pleural cavity without the admission of air. The apparatus consisted of a trochar and canula much longer than that usually employed for paracentesis abdominis. In the middle of the canula a stop-cock is placed, which is to be turned to cut off the admission of the external air, before the trochar, which is accurately fitted to the tube, is completely withdrawn. The shoulder of the canula is constructed for adaptation to Reid's syringe, by which the fluid is to be removed.

THE SEDATIVE POWERS OF ERGOT.

By Q. GIBBON, M.D., of Salem, N. J.

I AM induced to offer for your consideration the following remarks upon a singular pro-

perty possessed by the ergot—that of diminishing the frequency of the pulse—by a desire to see the truth of the subjoined facts either verified or disproved by further experiment.

Having occasion during the summer of 1841 to prescribe the ergot in a case of menorrhagia, I observed a manifest decrease in the frequency of the patient's pulse. Surprised at a result which, from my previous knowledge of the properties of the remedy, I was unprepared to anticipate, I was induced to test by further experiment its reality.

With this view I gave on the 19th of June, 1841, sixteen grains of pulverized ergot in decoction to a healthy man 20 years of age, whose pulse at the time of exhibition was 64. He had maintained the sitting posture an hour previously, and continued it during the experiment.

Results of Experiment.—20 minutes after exhibition, pulse 58, moderately full; 30 minutes after exhibition, pulse 48, small; 45 minutes after exhibition, pulse 48; 60 minutes after exhibition, pulse 52; 75 minutes after exhibition, pulse 55. The experiment was here concluded, and the patient permitted to walk about—6 hours after exhibition, during which he took his dinner, his pulse was at 60.

2d Experiment, June 20th.—The same individual, and sitting as before, took a scruple of ergot in well-boiled decoction of two waters, pulse 60; 15 minutes after exhibition, pulse unchanged; 25 minutes after exhibition, pulse 52, full and tense; 35 minutes after exhibition, pulse 51; 45 minutes after exhibition, pulse 51; one hour after exhibition, pulse 54; one hour and a half after exhibition, pulse 56.

3d Experiment, July 3d.—Gave the same with pulse at 64, a decoction of one drachm of ergot; 20 minutes after exhibition, pulse 52; 30 minutes after exhibition, pulse 46, slight nausea; 40 minutes after exhibition, pulse 45, nausea increased; 5 minutes after vomiting occurred, after which pulse rose to 60; one hour after exhibition, pulse stood at 46, with slight nausea; 2 hours after exhibition, pulse 50, no nausea.

4th Experiment, Aug. 7th, 1842.—Took myself 10 grains of a watery extract, prepared by boiling 3j. of ergot in a pint of water, and evaporating to a consistency proper for pills. Pulse, at the time of exhibition, 70; 30 minutes after exhibition, pulse 60; one hour after exhibition, still 60; one hour and a half after exhibition, pulse 57; three hours after exhibition, pulse 60.

5th Experiment, July 29th, 1843.—Took 30 drops of the oil of ergot, prepared by digesting the powder in ether and evaporating the liquor. Pulse at exhibition, 70; 30 minutes after exhibition, pulse 64; one hour after exhibition, pulse 60; two hours

after exhibition, pulse 56; three hours after exhibition, pulse still 56.

The only work in which I recollect to have seen this sedative property of ergot noticed is that of Collins's *Midwifery*, page 156, in which it is mentioned as being very striking in almost every case where administered during labour. I have frequently watched its operation upon the female system under similar circumstances, but have never witnessed such well-marked effects as are mentioned by that author. A decrease of four or five pulsations in the minute is as much as I have been able to discover. I have obtained the most satisfactory results from the operation of the agent upon the unimpregnated female and upon male subjects. It is but reasonable to suppose that the excitement of labour would materially interfere with the exercise of this peculiar sedative property.—*American Journal of Medical Sciences*, Jan. 1844.

CASE OF FATAL HEMORRHAGE

FROM PERFORATION OF THE ARCH OF THE AORTA, BY FALSE TEETH IMPACTED IN THE OESOPHAGUS.

By JAMES DUNCAN, M.D.

Surgeon to the Royal Infirmary of Edinburgh.

A YOUNG man, aged 22, a dentist's workman, having lost his two front teeth by an accident, supplied the deficiency by a couple of artificial teeth secured on a frame in the usual way. He sometimes slept with these teeth in his mouth. On the 28th of February last they were missing in the morning, and the young man complaining of pain and difficulty in swallowing, he applied to Mr. Syme, who with a probang detected a foreign body in the oesophagus, much beyond the reach of the ordinary forceps used for extracting foreign bodies from the gullet. The patient was removed to the Infirmary, and attempts were made to entangle the foreign body in a skein of thread connected with the probang, but in vain. By and by the pain subsided, and the patient left the hospital in the evening of the 9th day, March 8th. Next morning Dr. Duncan was hastily summoned to see him at home. In rising from bed, and crossing the room, he had become suddenly faint and giddy, and had vomited a mouthful of blood. He was immediately removed to bed, and complained of a feeling of great weakness, and of some slight difficulty in breathing. His face was pale, and the skin rather cold, but the pulse was of moderately good strength. From his description of what had taken place, I was led to believe that the foreign body had been dislodged from its situation, and that it was possibly within reach of the forceps, with which I had provided myself. I accordingly requested him to sit up by the

side of his bed, to enable me to make the necessary examination. This he did with ease, and without much assistance, expressing great anxiety to have something done to relieve him. The act of depressing the tongue, to enable me to introduce the forceps, produced vomiting, and a mouthful of dark fetid blood was discharged. This was immediately followed by another but much larger quantity of fluid of the same description, perhaps about eight or ten ounces, and the false teeth were heard to rattle against the vessel into which it was received. The patient was immediately aware of this, and his friends were overjoyed at what had taken place. Another mouthful of the same fluid was then ejected: an interval of a few seconds elapsed, and then a mouthful of bright arterial blood was discharged; a second, and a third followed, the lips became livid, the pulse at the wrist ceased, the patient gave one or two convulsive sobs, and expired.

An inspection of the body was readily obtained from the friends. The pharynx, the oesophagus, and stomach, along with the carotids, subclavians, and arch of the aorta, were removed entire, a ligature having been previously thrown around the duodenum to prevent the escape of the blood which had accumulated in the stomach, and so enable us to form an estimate of the quantity which had been lost. The oesophagus, stomach, and duodenum, were found distended with pretty bright arterial blood. The quantity could not be measured; but in the opinion of those present at the examination there could not have been less than eight or ten pounds. The pharynx and oesophagus were laid open by an incision posteriorly, carried as low as the cardiac orifice of the stomach. About $4\frac{1}{2}$ inches from the rima glottidis there was an ulcerated perforation of the anterior part of the oesophagus, of about $\frac{3}{4}$ ths of an inch in length and three lines in breadth, passing obliquely upwards from the right to the left side. The edges of the perforation were rounded, and there was considerable surrounding injection of the mucous membrane. By this opening the probe could be readily passed into the aorta; but the latter vessel was not laid open at the time, it being thought better to immerse it for a day or two in spirits before doing so. On laying open the aorta subsequently, a perforation of about the size of a large crowquill was found about half an inch below the origin of the left subclavian artery. The opening was irregular in form, the edges everted, and at the lower part there was a pretty firm adherent coagulum. There was little or no vascular injection around this opening. The artery was otherwise perfectly healthy.—*The Northern Journal of Medicine*, No. 1, May, 1844.

ON THE
ELEPHANTIASIS GRÆCORUM
ENDEMIC IN CERTAIN PARTS
OF NORWAY.

By D. C. DANIELSEN, M.D.*

Greek leprosy, once so common among the Israelites, and which in the middle ages was endemic over the whole of Europe, and appears to have been particularly common in Great Britain,† prevails at this moment in Norway, probably with as much severity as ever. In a population of 200,000, 1200 are actually lepers.

Greek leprosy presents itself especially along that portion of the western coast of Norway which is comprised between the 60th and 70th degrees of North latitude, among the poorer classes of the community; it is hereditary, but does not attack every member of the family when one is invaded; it is not contagious, but its severity appears to increase with the number of generations which have suffered from it. Its invasion is determined by accidental external circumstances. No age gives immunity; that form which presents the tuberculous character is evolved in the foetus, and has been seen in a new-born infant. It may arise in a healthy individual, born of healthy parents, living under the influence of the conditions which favour its evolution; these conditions being especially damp and dirty clothes, small and ill ventilated houses, exposure to the thick fogs of the country, indifferant food, and the other accompaniments of poverty.

Greek elephantiasis, or leprosy, presents itself under two forms in Norway—El. tuberculous, and El. anæsthetica, but the two forms occur together, and also complicate other diseases of the skin, such as eczema, prurigo, lichen, &c.

In the bodies of those who fall victims to the disease—and its tendency is invariably towards a fatal termination—hard, yellowish, and granulated masses are found in the substance of the dermis, and in the subjacent cellular tissue, which destroy the structure of these textures. The same alteration occurs in the greater number of organs—in the parietes of the subcutaneous veins, in the coats of the eye, the larynx, trachea and bronchi, pleura, liver, spleen, intestinal canal from top to bottom, and the uterus: strangely enough, the substance of the lungs is generally exempt. In a few cases of El. anæsthetica, the skin in several places was found very much atrophied, the subcutaneous cellular tissue and the muscles almost entirely destroyed, and the tendons in some places retracted.

* Comptes Rendus, Avril 1, 1844.

† See the interesting papers of Dr. Simpson, of Edinburgh, on the subject, in the Edin. Med. and Surg. Journal.—Ed. Gaz.

The therapeutical means hitherto opposed to this frightful disease have had little or no influence—it is commonly and inevitably fatal.

APOTHECARIES' HALL.

Gentlemen who have obtained certificates, May 30.—C. Hill, Ireland.—T. Blatherwick, Litchfield, Hants.—J. C. Croft, Sherborne, Dorset.—E. O. Golding, Ditton, Kent.—H. B. Pickens, Hadleigh, Suffolk.—C. Robinson, Bradford, Wilts.—L. White, Breckon, Somerset.—C. A. Wakefield, Ludlow, Salop.—H. Wright, East Bridgeford, Notts.

TO CORRESPONDENTS.

Dr. Buchanan's interesting papers have been received, and will afford us matter for comment immediately.

Mr. Paterson will find his case in the present number.

We have the honour to acknowledge the receipt of a packet from the Director-General of the Army Medical Department, containing two papers: one on Tubercular or Greek Leprosy, now prevailing in a district of Lower Canada, by A. S. Skene, Esq., 52d Foot; the other a case of Diseased Testicle, with observations, by A. S. Santer, M.A., 7th Fusiliers.

ON
TUBERCULAR LEPROSY.

By A. S. SKENE,
52d Foot.

COMMUNICATED

By SIR JAMES M'GRIGOR,
Director-General Army Medical Department.

(For the Medical Gazette.)

HAVING been appointed, by the Lieut.-Governor of New Brunswick, one of a commission, consisting of Dr. Toldervy, of Fredericton, Dr. Key, of Chatham, Dr. Gordon, of Bathurst, and the Rev. Mr. La France, P.P. of Tracadie, to investigate the condition of Tracadie and the adjoining districts, with reference to a malignant disease reported to prevail therein; I have to state that, having, in terms of the above-mentioned commission, proceeded to the districts in question, the disease alluded to proved to be the TUBERCULAR LEPROSY, or Elephantiasis of the Greeks.

On comparing the symptoms of the cases submitted to us, with those of the lepra tuberculosa, in Bateman, Simpson, Copland, and others, I satisfied myself that this disease was the tubercular leprosy, and that their descriptions of it left little to be desired.

Deeming myself peculiarly fortunate in having thus had an opportunity of personally observing a disease so rare, and so little known to British authors, and one which presents numerous points for inquiry to the philosophical mind, I have thought it best to confine my remarks—

First, to the proof that the cases observed were really the lepra tuberculosa of authors.

Second, to the particular points still at issue in regard to the history of this remarkable malady.

In regard to the first point, I shall quote 863.—XXXIV.

the definition of this disease of Dr. Copland, p. 701 of his valuable Medical Dictionary.

"1. Definition.—Dusky-red or livid tubercles, of various sizes, on the face, ears, and extremities; thickened or rugous state of the skin, diminution of its sensibility, and falling off of the hair, except that of the scalp; hoarse, nasal, or lost voice; oozæna; ulcerations of the surface, and extreme fœtor."

This definition will, I think, be amply borne out by the following cases, selected from nineteen which came under my own observation.

1. Frances Savoy*, aged 46, a married woman, with a family of six children.

When I saw this patient, on the 28th of March last, she presented the following appearances:—

The whole surface of the skin seemed as if smeared over with oil. The whole of the face was studded with tubercles, varying in size from that of a pepper-corn to that of a bean; the larger ones about the lower part of the face, where they became confluent, and caused much enlargement of the lips, and the cheeks to be pendulous. This enlarged mass, particularly under the chin, is divided by numerous rugæ, more especially by a transverse one, larger than the others, giving (or causing) the appearance of what is commonly called "double chin," in a very remarkable manner. Nose very much enlarged,—also pendulous, with ulceration commencing at the lower part, its mucous membrane excessively thickened; the eyebrows are devoid of hair, and the cilia have almost entirely disappeared. The whole of the inside of the mouth and fauces is studded with tubercles of various sizes, confluent about the velum and uvula. Voice husky and nasal. Breath intolerably foetid. Many tubercles, of various sizes, were seen on the upper and lower extremities. Respiration short, and she coughs a good deal. Sleeps well, and eats well, and suffers little or no pain. Dis-

* This case was seen in the Neguac Settlement.

case made its first appearance four and a half years ago. Her husband sleeps with her every night, and is in perfect health, but one of her sons, a boy eight years of age, is affected with this disease.

2. Tranquil Robichaux*, a boy aged 15. On the 29th of March, 1844, he presented the following appearances:—

The whole of the face much swelled, and the surface of the skin seemed as if smeared over with oil—studded with tubercles, very large, about the lower part of the cheeks and chin. Tip of the nose pendulous, and abraded, occupied by a livid, shining tubercle. Lips enormously enlarged, and full of tubercles on the inner sides, which have the appearance of small cicatrices on their summits. Tongue much thickened, and protruding between the lips, with numerous fissures crossing each other in different directions, and full of tubercles. Palate and whole of the fauces thickly covered with tubercles, small, and confluent. Uvula and tonsils extensively tubercular; in fact, one mass of disease extending down into the pharynx. Constant cough. Breath very offensive; voice a mere whisper; and when raised by extraordinary exertion, not like that of a human being. Hair from eyebrows and eyelids entirely gone. Extensive ulceration on the calf of the left leg, and also on the right instep, with incipient ulceration about the roots of the nails. Large oblong tumor in either groin, presenting somewhat the appearance of femoral hernia. Four large but superficial ulcers on the left thigh, with thickened and indurated edges: trunk of the body free from tubercles.

Sensibility of all the diseased parts very much impaired, if, indeed, not entirely destroyed, inasmuch as I pinched them as hard as I possibly could, without inducing any pain.

Sleeps indifferently—appetite good, and digestive organs apparently unimpaired. The disease commenced six years ago; his uncle died of this disease about a month ago, in, I was told, a shocking state.

3. Peter Savoy†, aged 33, married; his wife and four children are all apparently healthy.

Appearances presented by this patient on the 3d of April, 1844.

Countenance of a dirty, livid complexion, mottled and shining, as if smeared over with oil. Tubercles of various sizes studded over the forehead—smaller on the upper part of right cheek.

Nose much swollen, with an enlarged state of the left ala more particularly, which is of a livid colour, possessing a very glossy surface. A large tubercle arising from the

septum, filling up the left nostril; mucous membrane much thickened. Upper lip full of large tubercles, which are superficial, and give the mouth a corrugated appearance. Eyebrows much enlarged, and overhanging, devoid of hair; and that of the cilia almost wanting. Conjunctiva slightly injected. Skin of eyelids, and that covering the malar bones, of a yellowish, tawny, or copper colour. Palate of a darkish yellow, and in some places, of a livid colour. Breath extremely foetid. Voice hoarse and husky. Ears tubercular and pendulous.

Chest and arms covered with livid blotches. Tubercles thickly studded over the outer and posterior surfaces of the fore arms. One or two on the right have suppurated, and are now covered with dark scabs, with white scaly edges. Hands dry and shrivelled, with skin on the palms horny, and cracked. Nails tolerably healthy. Lower extremities (thighs and legs) covered with the same livid blotches as those described on the arms. Inguinal glands of both sides enlarged. State of the feet same as that of the hands.

He states that seven or eight years ago he fell out of health, and became affected with apathy, debility, drowsiness, and slight occasional irritation in the skin. These symptoms continued for two or three years, when blotches showed themselves, of a darkish yellow, or tawny colour, on the face, chest, and extremities, and these (blotches) in the course of some months became of a dusky red or livid colour. About a year afterwards, tubercles (or lumps, as he described them) made their appearance. The first of these developed itself over the left eye, and they have gradually extended themselves as has been described.

4. Alexander Stewart*, aged 49, unmarried, presented the following appearances on the 3d of April, 1844:—

Complexion dirty and unhealthy, and the surface of the skin seems as if smeared over with oil.

Face mottled, studded with flattened tubercles, none very superficial; the whole of the integuments thickened, with uneven surface.

Eyebrows full and drooping, perfectly devoid of hair; that also of the cilia almost gone. Lips thickened, and their inside covered with small tubercles with white summits.

The whole of the throat and palate covered with confluent tubercles; superficial ulceration extending down the pharynx as far as can be seen; two or three tubercles on the back part of the tongue, which is much thickened; breath very foetid; voice a mere whisper, with laborious breathing; occa-

* This is one of the cases in the Tracadie district.

† This case we saw in the Tabisiatuc settlement.

* Eighteen miles up the north-west branch of the Miramichi river.

sional cough, with a bloody mucous expectoration.

His beard is so thin, that he can go three weeks without shaving, and suffers no inconvenience therefrom. The whole surface is covered with a dark reddish eruption, more particularly on the upper part of the chest and extremities: (here the peculiar oily appearance is very remarkable).

Skin of hands much shrivelled and cracked. Several detached tubercles on the calves of the legs and insteps, accompanied with great want of muscular power. Toes swollen, and of a glossy livid colour; nails furfuraceous, and almost gone. The sensibility of the surface is very materially diminished—pinching the integuments of the face and extremities causing little or no pain: to use his own expression, "My flesh seems as if it were dead."

Appetite good, but passes very restless nights, and is altogether in a debilitated condition.

He states that about eight years ago a rash appeared on his body, which was considered by his friends to be itch: this rash was confined to the extremities. In the course of some four or five months this rash in a degree disappeared, and was followed by swelling of the whole of the integuments; some of the glands in his neck also became enlarged. By and by numerous tubercles (or lumps, as he called them) presented themselves upon his face, and have since gradually spread.

I trust that the foregoing extracts from our case-book will satisfy you that the disease which we saw is identical with the tubercular leprosy which prevailed throughout Europe during the middle ages, and which has more recently been seen in Iceland, the Faroe Isles, Shetland, Holstein, Madeira, the Crimea, Africa, Ceylon, (vide Staff-Surgeon Kinn's Paper, Edinburgh Med. and Surg. Journal, No. 52,) and the East and West Indies.

The new locality for this disease forms a part of the province of New Brunswick. It is chiefly confined to the east side of the land lying between the Bay of Chaleur and the estuary of the Miramichi River, and more particularly to the settlements on the Neguac and Tracadie Rivers.

We could not draw any *positive* conclusion as to the original appearance of the disease in this quarter, but, from statements submitted to us by some of the oldest settlers, we learned that the first case occurred about the year 1817, in the person of a woman named Ursale Landré, one of a family of nineteen children.

The father of this family is supposed to have been an Acadian, and married a woman of Carriacou of the name of Mary Bredeau.

Ursale Landré married a man of Tracadie, of the name of Joseph Benoit, about the year 1798 or 1799.

Ursale and her husband came to reside in Tracadie immediately after their marriage, and had five children—three daughters, and two sons. Ursale is known to have been a perfectly healthy woman until after the birth of her youngest child, which took place in 1809. She continued in delicate health for six or eight years; and it was observed about this period that spots or blotches developed themselves on the face, extending over the upper part of the trunk and extremities.

After a lapse of time, distinct lumps (as they described them) appeared on the face, and on the inside of the lips, and in the throat. She lost the hair of her eyebrows and eyelashes; the voice became hoarse and husky; and, in short, she appears to have exhibited all the characteristic symptoms of the disease, and died in 1829.

Joseph Benoit, her husband, took the disease three or four years before her death, and sank under it in 1831.

From these cases the disease would appear to have gradually extended itself; and although, ten or eleven years ago, only two cases existed, we found, independent of seven deaths* which have occurred, thirteen confirmed cases in Neguac, one confirmed case in Tabisiutac, and one (Alexander Stewart) eighteen miles up the north-west branch of the Miramichi River, making in all nineteen.

The points still at issue, and which appear to be of interest connected with this disease, relate to,—1st, its peculiar nature; 2d, the pathology; 3d, the causes; 4th, the diagnosis; 5th, the prognosis; 6th, the treatment. The remarks which I am enabled to make on these subjects are far from being complete, but being the results of individual observation and reflection, may be taken for what they are worth.

With regard to the first point, I am led to think that the primary cause of all the symptoms detailed in the foregoing cases, and also of the others submitted to our inspection, was a morbid principle, *sui generis*, known only by its effects, which most probably resides in the blood—the common pabulum of the organs, being generated therein by a virus, which, when once introduced, reproduces itself, and, by degrees, transforms the normal elements of blood into new compounds, which contaminate the whole system, and control the innervation, and all other vital influences: the most pro-

* These deaths are exclusive of five others, who are known to have contracted the disease in Tracadie, but died elsewhere. Dr. Key saw these cases, and asserts most positively that they died of this disease.

ninent symptoms being a perversion of nutrition, together with the secretion of new products in the tissues of organs.

The determination of the specific chemical changes, and the attendant anatomical lesions, must necessarily be left to the medical officer who will be appointed to superintend the infected districts. It is also desirable that experiments be instituted upon the lower animals, as to whether the morbid poison can be introduced into the system through wounded surfaces, or by absorption from the stomach. As bearing upon this point I may state, that while at Tracadie I was told that a case had been produced by sanious matter, which had escaped from the coffin of a person deceased of this malady, and which had come into contact with the shoulder of one of the bearers.

2d. As to the morbid anatomy.—Having had no opportunity of making post-mortem examinations, I refrain from making any remarks upon this subject, further than to refer you,—first, to my general views in regard to the peculiar nature of the disease; and second, to what may be gathered from the cases which have been detailed.

3d. In regard to the causes of tubercular leprosy, I have already said that the disease, in my opinion, depends upon the introduction into the system of a specific morbid poison; and the question comes to be,—first, how this poison originates? and second, as to how it is communicated? As has been stated, there are no means of deciding upon the mode in which Ursule Landré first contracted the disease; but no doubt rests on my mind that it has since been from her communicated by hereditary taint, and by contagion. From genealogical inquiries I was induced to draw the first of these conclusions; and the other persons affected being in the habit of associating with the diseased families, may serve to justify me in regard to the second point. After all, perhaps, hereditary transmission may be only a peculiar modification of contagion. At all events, the one is not opposed to the other: and I do not think that the disease, which is at present local or endemic, is likely ever to become epidemic; for, as appears by the report of the Guadeloupe Commission, in 1748, "the contagion is not so active nor poisonous as that of the plague, small-pox, nor even as the ring-worm, itch, scald, and other cutaneous disorders; for, if that were ever the case, the American colonies would be utterly destroyed."

The facts stated above will also show that all those brought into direct contact with the disease, and all those immediately connected with the sources of the malady, do not necessarily become affected with it; so that I am forced to conclude that, in the cases which became affected, there existed

either some intrinsic constitutional peculiarity, which predisposed them to the disease; or, that they were exposed to certain extrinsic causes, which rendered them peculiarly liable to its attack.

I do not pretend to decide upon the intrinsic causes, but those which authors suggest are,—depressing mental affections, age, and sex.

In regard to the first of these heads I have to say that our examination afforded us no evidence worthy of special notice; and concerning the second I have only to remark, that the ages of the patients we saw varied from eight to forty-nine years; and that, whereas Mr. Stewart's cases, quoted by Dr. Copland (page 706 of his Medical Dictionary), go to prove that women are less liable to this malady than men, our observations show that the male were to the female cases in the proportion of twelve to seven; so that on the whole, perhaps, I am justified in saying, that both sexes are equally susceptible of the affection*.

The extrinsic causes cited by authors are,—indigence, including filth, exposure to extreme temperatures, scanty or unwholesome food, together with miasmata generated in the soil or subsoil.

I have no doubt that indigence, filth, and scanty diet, predispose to contagious diseases of every description, and whether in this instance unsound wheat, rye, potatoes, or fish, are to be blamed, I regret to say that my opportunities did not allow me to determine; however, there is strong reason to believe that the fish, which forms the principal article of diet of the people in the infected districts, is often in a state of decomposition before being salted: but supposing, as is asserted, that in imperfectly cured fish there is a special organic poison, the operation of boiling ought most probably to render it innocuous.

With reference to the miasmata and the

* I may here give the names of the different lepers whom we saw, beginning with the

geological structure of the districts in question, I have reason to believe that there is nothing particular.

4th. *The diagnosis.*—On referring again to Dr. Copland's definition of this disease, it will be seen, that in the advanced stages the symptoms are so well marked that little difficulty can occur in detecting it; while in the earlier, I can only say, that the peculiar tawny discoloration of the palate and fauces appears to me, in the absence of tubercles, characteristic of the malady. It cannot be confounded with acrofula, inasmuch as this latter symptom is never present; nor with scurvy, inasmuch as there is no tendency to local hæmorrhage; nor with syphilis, which is originally a local affection; nor with dry gangrene, which chiefly affects the larger joints. (*Vide* Dr. Charlton Wollaston's cases, recorded in the Phil. Trans., abridged, v. xi. p. 626.)

5th. *The prognosis.*—I am again obliged to say, that while our opportunities of observation do not allow me to bring forward any thing definite upon this head, and while ancient authors uniformly return the disease as incurable, the view which I have taken of the malady leads me to hope that the assimilation of the virus may probably be accelerated and accomplished before the constitution has given way; that is, before organs essential to life have become irretrievably obstructed; the external evidence of this fatal state being intimately connected with the development of tubercles in the superficial tissues.

6th. *The treatment.*—This is either active, palliative, sanatory, or preventive. With regard to the two first, the commission did not feel authorised to offer any observations to the government of New Brunswick; while in respect of the two latter, they unanimously recommended the erection of a lazaretto, strict seclusion of the lepers in this establishment, and legislative sanction for the removal of those patients who, while medical authorities were adjusting their differences, might introduce the seeds of a most loathsome malady into one of the most populous districts (Chatham) of this flourishing colony.

Before concluding this paper, I would beg particularly to refer you to "An Account of a Visitation of the Leprous Persons in the Isle of Guadaloupe, by John Andrew Peyssonnel, M.D. F.R.S. translated from the French, dated August 10th, 1718," reported in the Phil. Trans., abridged, v. xi. p. 74.

I have the honour to be, sir,
Your most obedient humble servant,
A. H. SKENE, A.S. 5 Q.L.I.

[We beg to refer our readers to our last number for a brief notice of the Greek

leprosy as it occurs in Norway, by Dr. Danielsen. It is interesting to observe this formidable disease showing itself upon the opposite shores of the Atlantic, in nearly similar geographical positions, and probably under very similar circumstances in regard to mode of life, food, &c.—Ed.]

ON

FRACTURES OF THE VERTEBRÆ.

By W. LYON,

Lecturer on Surgery, and lately one of the Surgeons of the Glasgow Royal Infirmary.

(For the Medical Gazette.)

CASE I.—*Fracture of vertebra—great displacement—Complete division of spinal cord—Death, eight weeks after injury.*

Matthew M'Lusky, æt. 24, blacksmith; admitted April 8th, 1842. Yesterday, at 5 afternoon, when running rapidly down a steep hill, he stumbled, and was thrown violently forward, pitching upon his head, and turning "heels over head." Complains of pain between shoulders, extending into chest, and somewhat impeding respiration. Lower extremities completely paralysed and insensible, as are likewise all the parts below the umbilicus, above which slight sensibility exists and becomes more perfect upwards. Power and sensation of upper extremities nearly, if not altogether, perfect. Respiration performed almost entirely by diaphragm; voice weak and hollow; inability to cough loudly. Spinous processes of the three superior dorsal vertebrae are moveable, and crepitate on being pressed: *scarcely any appearance of displacement*: bladder not emptied, nor bowels moved, since accident.

He was ordered to have the urine drawn off two or three times daily; to be placed in the position in which he felt easiest; and to have an opiate every night.

In a day or two after admission there was much pain and some swelling in site of injury; pulse 108, and full, abdomen tympanitic, urine ammoniacal, and bowels confined. A few leeches were several times applied over the pained part of back, and it was occasionally fomented. Paralysed parts were freely rubbed three times a day, and air-pillows placed below him where the pressure of body was greatest and most frequent: he was dissuaded from moving more than was absolutely necessary, and bowels were relaxed by small doses Sp. Terebinth. and Ol. Ricini. On the 11th, pulse was 84, and soft; tumefaction diminished: he felt comfortable, and his appetite was good. Neither at this nor any other time could motion be excited, or sensibility elicited in the paralysed parts by pricking, tickling, or the like.

He continued in nearly the same state until the 9th of May, when he had a rigor, after which the pulse became frequent, and the appetite diminished. By the 29th of May, although he had used the air pillows, lain for some time on a hydrostatic bed, and been regularly rubbed, large bed-sores had formed over the trochanters and sacrum. He now became feeble, had frequent rigors and profuse perspirations, was much annoyed by cough, and, from paralysis of most of the voluntary respiratory muscles, was unable to expectorate the copious mucus collected in bronchi, and thereby suffered much distress from difficulty of respiration. The debility rapidly increased, the large sores were extending; pulse was 120, and small; cough, and difficulty in breathing, were very great, emaciation extreme, and perspiration profuse. He had whiskey, wine, ether, *lac ammoniaci*, &c., with very little advantage, and died on 17th of June.

Inspection.—The injured part of the spine, and portions above and below it, were removed and divided by the saw from behind forwards into two equal portions.

The spinous and oblique processes of several of the superior dorsal vertebræ had

FIG. I.—Section of Spine from *M. Lusty*.

- A. Broken body of vertebra, carried forwards and downwards.
- B. Spinous process fractured, and tilted upwards.
- C. C. Extremities of divided cord.

been fractured, lay confusedly together, and were connected by dense tissue, approaching in some points to cartilage. The body of the third dorsal vertebra had been fractured obliquely forwards and downwards, its spinous

process broken, one part of its body carried forwards for nearly two inches, and likewise downwards for about the same distance, so that the extremities of the fractured spine overlapped each other for an inch and half; the posterior aspect of the upper portion resting on the anterior of the lower, and the broken spinous process of the upper portion supported on the fractured body of the lower one, as shewn in Fig. I. The fractured portions were held together firmly in front, and at the sides, by condensation and agglutination of the surrounding tissues.

The separation of the fractured surfaces being so great, the spinal cord was of course completely divided, its extremities separated for more than an inch, and covered by membrane; they were injected, soft, and the membranes red and thickened. Further examination was not permitted, so that the condition of the aorta and other parts in front of the spine, which must have been much changed by the osseous displacement, could not be ascertained.

CASE II.—Fracture of spine—Paraplegia—Partial recovery—Death, eight weeks after injury—Morbid appearances.

Francis M'Gill, aged 27, collier, admitted October 3d, 1842. Five days ago was crushed between two railway waggons, the lower part of back being chiefly injured. Injury was immediately followed by complete loss of sensation and motion below the part which suffered violence, and likewise by inability to pass urine or retain stools, all which conditions continue. A considerable projection of spine is observed about situation of tenth dorsal vertebra, where he complains of pain, especially on pressure, but no crepitation can be perceived. Has been bled from the arm, and leeches over seat of injury.

In this instance, the pulse, for a considerable number of days after admission, did not rise above 84; and by the 9th, six days after admission, had fallen to 60. The pain at injured part was not at any time very severe, and was relieved by leeches and fomentations. The most troublesome symptoms were cough and copious mucous expectoration. As usual in such cases, tympanites early shewed itself; and, although every care was taken, by occasional change of posture, the use of air pillows, and friction with the hand three times a day, by the 6th, three days after he entered the hospital, and eight from reception of the injury, vesications had formed on those parts of the limbs exposed to pressure.

Oct. 9th.—Cough still more annoying; injured part feels easy; but, now that swelling is removed, there appears unequivocal prominence of several of the spinous processes; pulse 72; abdomen still tympanitic,

but relieved by action of turpentine and oil ; otherwise unchanged.

About this time he was placed upon a hydrostatic bed. Upon the 30th, general health is reported tolerably good, and it is stated that, last night, he had a feeling of heat in limbs, and to-day can slightly move toes of right foot. The power of motion did not increase ; but, on the 2d of November, when the toes were pricked, although he did not feel the pricking, strong starting of the feet was occasioned.

He continued in the same condition for several days, when he felt return of pain in injured part of spine. His health now began to give way ; frequent rigors, followed by drizzling perspirations, occurred ; the clonics extended, although he still lay on the hydrostatic bed, and on the 7th of November are reported to be four inches in diameter over the points of the ilia, and also over sacrum.

He soon lost capability of moving toes,

FIG. II.—Section of Spine from M^r Gill.

A. Edge of osseous case.
B. C. Parts on which the cord was compressed.

and of having motion excited by pricking ; the symptoms were daily aggravated, and he died at 10 A.M. of November 20th, being a day more than seven weeks after admission, and nearly eight from period of receiving injury.

Inspection.—Not any diseased appearance, excepting at injured part of spine, where a fracture was found extending from side to side, obliquely, through body of eleventh dorsal vertebra ; the superior articulating processes were also broken, the spinous process of the tenth vertebra forced up, and its body carried forward the third part of its breadth, thereby narrowing the spinal canal at that point, and stretching and pressing upon the cord, which was much softened, and its membranes thickened and separated by effusion. A small part, also, of left side of vertebral canal had been broken up, and a fragment was placed across it, with its sharp edge resting on the cord. (See Fig. 2.)

The portions of the bodies of the fractured and displaced vertebrae were held together at the sides and front by osseous matter in such quantity as nearly to encase them, and prevent more than very slight motion. The state of the ligaments was not ascertained.

CASE III.—Fracture of spine—Paraplegia—Rigors—Perspirations—Death, 17 days after admission.

Patrick Gallacher, collier, aged 37 : Dec. 27, 1842. Admitted at 5 P.M. To-day, while at work in a coal pit, a large stone fell from the roof, struck him on the back, and crushed him to the floor of the mine. Complaints of severe pain, much aggravated by motion, about region of central dorsal vertebrae, where there is some swelling, and slight appearance of spinal curvature towards right side, but, owing to tumefaction of soft parts, accurate discrimination is impracticable. There is entire loss of motion and sensation below seat of injury, and there is likewise retention of urine.

Such is the account drawn up by the clerk. Next day his condition was nearly similar ; and then examination was instituted, but crepitation could not be detected.

In this instance the symptoms were at first nearly similar to those detailed as existing in the two former patients—paraplegia, tympanites, ammoniacal urine. He likewise was leeches, and used air-pillows ; and, from the uncertainty as to whether fracture was present, and as upon the supposition of its absence mercury would likely have been beneficial by interrupting inflammatory action, and exciting absorption, he was ordered frequent small doses of calomel, which, however, were soon omitted, troublesome diarrhoea having supervened. On the 2d of January, eleven days after the accident, rigors occurred, followed by much

cussion and extravasation, uncomplicated with fracture.

The case of M'Lusky, in whom one portion of the fractured spine was carried completely in front of the other, while the deformity was, nevertheless, far from conspicuous, tends to shew that, in spinal fractures, the depth of the bones from the surface, and the thickness of muscular covering they possess, render the detection of these fractures less easy than reflection would have anticipated. Nor even when fracture is tolerably manifest, as in the instance of Gallacher, can correct deductions be drawn as to the seat or extent of the injury; for, in the case referred to, the injury to the spinous processes which were prominent was the least important of the osseous lesions, the oblique processes being likewise fractured, the articulating surface of one of the vertebræ broken off, and the vertebra above carried forward for a quarter of an inch, thereby diminishing the calibre of the spinal canal to an equal extent*.

The difficulty of forming a correct diagnosis is equally well proven by the third case, that of M'Gill. Here there was neither crepitation heard, though the stethoscope was employed, change of form observed, nor unnatural motion perceived; and yet there was fracture of so much more serious a nature than in either of the other cases, as to destroy the patient in less than a fourth of the time of the shorter-lived of the two.

So far as can be inferred from the three cases detailed, the prognosis is very unfavourable in cases of fractured vertebræ; and although the life of the patient be not destroyed by this species of injury, it very often, but not invariably, happens that sensation and voluntary power, generally lost from the moment the injury is received, are only partially restored; and oftener still, that they never in the least return; and the patient, often unable to retain his fæces or urine, incapable of locomotion but by exertion of his hands and arms, drags on a comfortless and hopeless existence, a nuisance and a burthen to himself and all his connections.

The function of respiration is the only one resident in the spinal cord, the entire interruption of which is

immediately destructive of vitality; and as that process is partly dependent on the phrenic, and partly on the spinal nerves, the *immediate consequences*, in fractures of the vertebræ, will vary as the injury is above or below the involuntary or diaphragmatic, or higher or lower in the spinal or voluntary nerves of respiration. But although the function of respiration be the only one presided over by the spinal contents, the interruption of which may be instantly fatal, the collection of mucus in the bronchi, the tympanitic abdomen, the ammoniacal urine, the sloughing of the soft tissues, in the patients whose cases I have detailed, shew that the spinal nerves perform other functions besides those of respiration, voluntary motion, and sensation, the interruption of which may materially aid in hastening the fatal result which so generally follows fractures of the spinal column.

If death be not occasioned immediately, or very soon, by the deprivation of important or extensive nervous functions, dangers to life arise from several sources — inflammation, softening, or suppuration of the spinal cord; or the first and latter of those actions in the sheath; or similar states in the intervertebral cartilages; and occasionally the involvement of all these parts at the same time.

Supposing the patient to escape from the risks specified, still, in consequence of pressure on the cord from displacement of the vertebræ; from the effects of undue deposition of callus, or effusions, which become organised; of induration or softening of the cord, &c.; sensation and power of motion never return, or return only in slight degrees; the vital powers of the paralysed parts are much diminished: indeed, it may be said that they do not possess more than vegetable life: from very slight pressure this is destroyed, and, upon separation of the resulting sloughs, large ulcers are produced, while the same causes still acting, the ulcers extend, and, from the consequent discharge and irritation, debility and death are much hastened, as in the cases detailed.

When we closely consider, then, the amount of injury done to the ligaments, the intervertebral cartilages, the bones, and still more to the spinal cord and membranes, and the consequent morbid actions induced in fracture of the spine

* See Fig. 2, letter B.

accompanied with displacement, as in two of the cases related, M'Lusky and M'Gill, we are at no loss to account for the serious terminations.

In both of these patients the displacement of the vertebræ at the seat of fracture was so considerable that the lateral ligaments were lacerated—in M'Gill partially, in M'Lusky completely; the anterior and posterior ligaments were likewise similarly injured.

In addition to ligaments, the vertebræ being firmly united to each other by the intervertebral cartilages, they cannot be displaced without tearing of the substance, or separation of the cartilages from the bones; and the cartilages becoming inflamed and ulcerated, we readily perceive why they were not found, and why the surfaces of the bones they had united are bare, soft, and approaching the state of caries.

In M'Lusky, in whom the fractured vertebræ overlapped for half an inch, thereby causing shortening to double that extent, the aorta, cava, and thoracic duct, must have been displaced anteriorly or laterally. No disturbance of the functions of these vessels was observed, and their exact conditions were not ascertained, permission to examine other parts than the fractured spine being refused in his case, and also in the other two patients.

In M'Lusky and M'Gill there was dislocation as well as fracture. We suppose that simple dislocation, from a blow upon the spine, or a fall on the head or feet, is next to impossible in the dorsal or lumbar vertebræ. We can conceive that the bones might be dislocated without fracture, by extension and counter-extension, or a blow directed obliquely upwards; but when driven past each other by a force acting transversely to the length of the spine, the articulating processes must inevitably give way; and where the spinous processes overlap, they, too, will generally be fractured. Again, there may be fracture of the processes with or without the bodies of the vertebræ being broken; but if there has been considerable displacement, either the *intervertebral cartilage* or *bodies of the vertebræ* must have suffered.

In the preparation from M'Lusky, the body of the third dorsal vertebra is seen to be fractured obliquely from

behind forwards and downwards, and a portion of it, with the vertebræ immediately above, carried in the same direction, and resting partly on the front of the first and second bones below. A portion of a spinous process is to be observed fractured and tilted up; and on the posterior aspect of the preparation, in the fossa between the spinous processes and detachment of the transverse processes and ribs, there is a confused collection of fragments, huddled closely together, seemingly portions of the transverse processes and posterior arches of vertebral canal.

The ribs attached to the vertebræ of the upper portion of the spine are carried downwards, forwards, and inside of those of the inferior portion; which relation of parts must have put the soft tissues behind much on the stretch, correspondingly relaxing those anteriorly.

There is only the slightest appearance of deposition of new bone around the seat of fracture, though the patient survived eight weeks after injury; and the parts appear to have been mainly held in connection, and motion to have been prevented, by condensation of the surrounding soft tissues, the remains of the ligaments and muscular attachments.

The inferior termination of the divided cord is seen an inch and a quarter before the superior extremity of the inferior portion. The extremities were slightly rounded, rather softer than adjoining portions, somewhat red, and covered by membranes. The membranes near the divided part were redder and thicker than in health, and there was a small quantity of blood between them and the cord.

In the preparation taken from M'Gill, the spinous, transverse, and oblique processes of the 10th and 11th dorsal vertebræ have been fractured, and are confusedly heaped together; the intervertebral substance between these two bones is removed, and the upper of the two vertebræ is carried forwards for a third of the diameter of the lower: spiculæ of bone shoot from the surface of the one vertebra to the other, but do not unite; osseous matter is likewise deposited around them, and under the lateral ligaments, and also under the ligaments passing from the transverse processes above to those immediately below.

cussion and extravasation, uncomplicated with fracture.

The case of M'Lusky, in whom one portion of the fractured spine was carried completely in front of the other, while the deformity was, nevertheless, far from conspicuous, tends to shew that, in spinal fractures, the depth of the bones from the surface, and the thickness of muscular covering they possess, render the detection of these fractures less easy than reflection would have anticipated. Nor even when fracture is tolerably manifest, as in the instance of Gallacher, can correct deductions be drawn as to the seat or extent of the injury; for, in the case referred to, the injury to the spinous processes which were prominent was the least important of the osseous lesions, the oblique processes being likewise fractured, the articulating surface of one of the vertebræ broken off, and the vertebra above carried forward for a quarter of an inch, thereby diminishing the calibre of the spinal canal to an equal extent*.

The difficulty of forming a correct diagnosis is equally well proven by the third case, that of M'Gill. Here there was neither crepitation heard, though the stethoscope was employed, change of form observed, nor unnatural motion perceived; and yet there was fracture of so much more serious a nature than in either of the other cases, as to destroy the patient in less than a fourth of the time of the shorter-lived of the two.

So far as can be inferred from the three cases detailed, the prognosis is very unfavourable in cases of fractured vertebræ; and although the life of the patient be not destroyed by this species of injury, it very often, but not invariably, happens that sensation and voluntary power, generally lost from the moment the injury is received, are only partially restored; and oftener still, that they never in the least return; and the patient, often unable to retain his fæces or urine, incapable of locomotion but by exertion of his hands and arms, drags on a comfortless and hopeless existence, a nuisance and a burthen to himself and all his connections.

The function of respiration is the only one resident in the spinal cord, the entire interruption of which is

immediately destructive of vit as that process is partly dependent on the phrenic, and partly on the nerves, the immediate consequences of fractures of the vertebræ, whether the injury is above or below the voluntary or diaphragmatic, or lower in the spinal cord, or nerves of respiration. But the function of respiration being one presided over by the spinal cord, the interruption of which is instantly fatal, the collection in the bronchi, the tympanum, the ammoniacal sloughing of the soft tissues, in patients whose cases I have shewn that the spinal nerve performs other functions besides those of respiration, voluntary motion, and the interruption of which materially aid in hastening the death, which so generally follows the fracture of the spinal column.

If death be not occasioned immediately, or very soon, by the fracture, of important or extensive nature, dangers to life arise from various sources — inflammation, suppuration of the spinal cord, the first and latter of those affections of the sheath; or similar states of the vertebral cartilages; and the involvement of all the above at the same time.

Supposing the patient to survive the risks specified, still, in the case of pressure on the cord from the fracture of the vertebræ; from the undue deposition of callus, which become organised; or softening of the cord, &c. and power of motion can never return only in slight degrees. The powers of the paralysed limbs are diminished: indeed, it may be said they do not possess more life: from very slight pressure being destroyed, and, upon severe pressure, resulting sloughs, large ulcers, while the same pressure acting, the ulcers extend, the consequent discharge, debility and death are the result, as in the cases detailed.

When we closely consider the amount of injury done to the intervertebral cartilages, and still more to the membranes, and the consequences induced in fractures

* See Fig. 2, letter B.

accompanied with displacement, as in two of the cases related, M'Lusky and M'Gill, we are at no loss to account for the serious terminations.

In both of these patients the displacement of the vertebræ at the seat of fracture was so considerable that the lateral ligaments were lacerated—in M'Gill partially, in M'Lusky completely; the anterior and posterior ligaments were likewise similarly injured.

In addition to ligaments, the vertebræ being firmly united to each other by the intervertebral cartilages, they cannot be displaced without tearing of the substance, or separation of the cartilages from the bones; and the cartilages becoming inflamed and ulcerated, we readily perceive why they were not found, and why the surfaces of the bones they had united are bare, soft, and approaching the state of caries.

In M'Lusky, in whom the fractured vertebræ overlapped for half an inch, thereby causing shortening to double that extent, the aorta, cava, and thoracic duct, must have been displaced anteriorly or laterally. No disturbance of the functions of these vessels was observed, and their exact conditions were not ascertained, permission to examine other parts than the fractured spine being refused in his case, and also in the other two patients.

In M'Lusky and M'Gill there was dislocation as well as fracture. We suppose that simple dislocation, from a blow upon the spine, or a fall on the head or feet, is next to impossible in the dorsal or lumbar vertebræ. We can conceive that the bones might be dislocated without fracture, by extension and counter-extension, or a blow directed obliquely upwards; but when driven past each other by a force acting transversely to the length of the spine, the articulating processes must inevitably give way; and where the spinous processes overlap, they, too, will generally be fractured. Again, there may be fracture of the processes with or without the bodies of the vertebræ being broken; but if there has been considerable displacement, either the *intervertebral cartilage* or *bodies of the vertebra* must have suffered.

In the preparation from M'Lusky, the body of the third dorsal vertebra is seen to be fractured obliquely from

behind forwards and downwards, and a portion of it, with the vertebræ immediately above, carried in the same direction, and resting partly on the front of the first and second bones below. A portion of a spinous process is to be observed fractured and tilted up; and on the posterior aspect of the preparation, in the fossa between the spinous processes and detachment of the transverse processes and ribs, there is a confused collection of fragments, huddled closely together, seemingly portions of the transverse processes and posterior arches of vertebral canal.

The ribs attached to the vertebræ of the upper portion of the spine are carried downwards, forwards, and inside of those of the inferior portion; which relation of parts must have put the soft tissues behind much on the stretch, correspondingly relaxing those anteriorly.

There is only the slightest appearance of deposition of new bone around the seat of fracture, though the patient survived eight weeks after injury; and the parts appear to have been mainly held in connection, and motion to have been prevented, by condensation of the surrounding soft tissues, the remains of the ligaments and muscular attachments.

The inferior termination of the divided cord is seen an inch and a quarter before the superior extremity of the inferior portion. The extremities were slightly rounded, rather softer than adjoining portions, somewhat red, and covered by membranes. The membranes near the divided part were redder and thicker than in health, and there was a small quantity of blood between them and the cord.

In the preparation taken from M'Gill, the spinous, transverse, and oblique processes of the 10th and 11th dorsal vertebræ have been fractured, and are confusedly heaped together; the intervertebral substance between these two bones is removed, and the upper of the two vertebræ is carried forwards for a third of the diameter of the lower: spiculæ of bone shoot from the surface of the one vertebra to the other, but do not unite; osseous matter is likewise deposited around them, and under the lateral ligaments, and also under the ligaments passing from the transverse processes above to those immediately below.

The case of bone thus formed is connected to the upper edge of the 11th, which is the fractured vertebra, and extends and is united to the upper margin of the 12th. Spiculae shoot from points of the interior of this osseous case to the sides of the 11th, which is thus enclosed in the case; but these points of attachment are not numerous or extensive. The osseous case is not perfect all around, but it is reasonable to suppose it would have become complete and strong enough to have held the vertebrae firmly together. It is rough interiorly, and externally is closely united to the ligaments which lie over it: it is about the thickness of strong pasteboard, and was so firmly connected as to prevent all but very slight motion at the fractured part. The vertebral canal is narrowed to nearly one-half its normal diameter; the cord was consequently compressed, and was also stretched from the elongation of the canal, by the one bone being carried before the other. The cord was soft, almost pulsatious where compressed: the membranes reddened and thickened.

It was stated that about an ounce of pus was found at seat of fracture: the pus was contained within the osseous case, and was probably secreted from the surfaces of the vertebrae at the seat of displacement, which have been already described as having been found carious: the membranes of the cord were consequently soaked in pus.

In this case, ossific ankylosis, and in so far the progress to a cure, had considerably advanced. Whether absorption of that part of the vertebrae projecting into the canal, and thus restoration of the functions of the compressed spinal cord, would ever have occurred, is I think very improbable: though some analogous-like processes have been observed in the cranium, where the sharp edges of fractured portions pressing on the brain have been found partially absorbed and rounded off, thus diminishing their injurious effects.

In the third case the main pathological appearances were similar to those in the other two. The displacement is much less considerable, there being only a very little in the axis of the bones, and a slight elevation of the one from the other, particularly behind: to permit this separation, the posterior lateral ligaments have partially given way, and the intervertebral cartilage has

been torn in its substance, or from its connection with the surface of the one or other vertebrae at injured part; which explains why it was found entirely destroyed, the injury done to it inducing inflammation and absorption, and leaving the bones bare, carious, and soaked in pus. The displacement in the axis of the spine being small, the cord was here only slightly stretched and compressed on the edge of the vertebrae below the one fractured; but the spinal canal was much narrowed, and the cord not only pressed upon, but penetrated by a sharp spicula detached from the lateral and posterior part of the osseous canal under the bases of the inferior oblique and spinous processes. (See Fig. 3.)

The extreme sharpness of the spicula, its great displacement, the point being thrown half across the canal, its consequent pressure on and wounding of the cord, the irritation, inflammation, and softening of the cord thus induced, explain the severity of the symptoms, and the rapidly fatal issue in this case.

[To be continued.]

ON CONSTITUTIONAL IRRITATION OR GENERAL DISTURBANCE.

By T. WILKINSON KING, F.R.C.S.E.

(For the Medical Gazette.)

[Concluded from page 337.]

We have adduced these facts to shew that the simply healthy frame is not much subject to the sympathies of pathologists.

There does not appear to be much difference between a severe crush and an extensive burn, as causes of collapse; and we may at least compare to these cases that of peritoneal extravasation. In all, perhaps, the pain precedes the collapse; there may be poisonous absorption in the last. In strangulated hernia and acute peritonitis we may find more or less of collapse; but these are far from being simple cases, and they are still less uniform. In the first we often seek to increase the depression; and in the last there is more of complication to be detected than in cases of painful inflammation elsewhere.

It is, of course, not to be concealed or disregarded, that particular pains or parts may be more concerned in the

origin of depression than others. The stomach and bowels, the testis and kidneys, when injured, may give manifestation of disturbance in manner and degree very different from that excited by violence to an extremity.

Here we would refer to a specimen* in the museum at Guy's, in order to explain a fact which is, perhaps, less uncommon than at first sight might be supposed.

A patient suffered very frequent attacks of pain about the right hypochondrium, which were extremely depressing, but which, after a certain continuance, suddenly went off. A stone had, to all appearance, been so circumstanced as to obstruct the commencement of the ureter, and, after a while, to fall back into the renal pelvis; and so on repeatedly. The pelvis was only moderately dilated, and the kidney was tolerably healthy.

Possibly the neuralgia of the ureter, described by some authors, may be explained by similar or equally physical facts. Catarrh, ulcer and stricture, and variable obstructions, are certain enough in the ureters†.

Rigor, Hunter makes to depend on "the novelty of an unaccustomed action or impression." We would rather impute it to feebleness in the patient, and to transitoriness of the cause or impression, whatever it may be. The rigor arises out of a certain state of the system (we would say, of the blood); and it is a fact, that rigor, sweat, and fever (if the attack of an habitual tertian is fever), are all equally harmless and fleeting. The cause of the relapse seems to take so many hours to accumulate or become efficient. The evils of fever consist in those more serious disorders which are not disposed of in an hour or two—bad blood, more or less fixed disturbances of functional balance, old and settled visceral disorganizations, and new supervening obstructions or inflammations.

A delicate youth, on a cold day, crushed the tips of two of his fingers between the cogged wheels of a capstan; he ran home with his teeth chattering, and lay on the sofa for many minutes in a sufficiently marked rigor-fit. No

other general disturbance followed, and the lacerations healed well.

An aged gentleman, from the tropics, went into the country, and was induced to pass part of the evening sitting in the garden; he was seized almost unawares with an alarming shivering fit, and his friends waited anxiously for the sequel. He arose in the morning as well as ever. Let us suppose the rigor induced in one liable to rheumatism or bronchitis, or who has much settled renal obstruction. Let the reader further simply consider what is certain enough in physical, and nervous, and humoral views, in the various forms of reaction, after cold, or fright, or bleeding, or injury, or merely after a sudden needful depletion. Then let him examine the hectic following each meal, and each tonic dose given to a wavering convalescent from fever, or in a declining case of open fracture or phthisical diarrhoea. He will see altered blood, and sensitive and motor nerves in action, and unsteady capillary acts and products. We do not assume that this is all he may discover; but we hold that this much is real, and that sympathy, if any thing *else*, is ideal as at present received, and a constant cause of stumbling in inquiry.

We would hope that it is unnecessary again to point to the needful course of analysing, or to the caution required in accepting, such prevalent reasoning as the following:—

"If painful news take away appetite, or pinching a tendon (? the skin over a tendon) occasion a sensation of sickness; if anxiety or apprehension excite the desire to pass stool or urine; if the sight of savoury food promote a secretion of saliva; if certain articles of diet provoke an eruption of the skin, or worms in the intestinal canal produce a temporary blindness;—the irritability of the affected organ is sympathetic." (Travers on Irritation, page 10.)

If it should ever be established, that there is one constitutional symptom proper to worms, or any general convulsion set up by teething, it will then appear how devoid all the preceding views have been of philosophic proof.

A splinter in the nerve of the thumb is said to cause trismus; but can we pass a harmless seton without an equal local intrusion upon nerves? The counter-irritation of a blister or a

* No. 20774*. Renal calculi found only in one kidney. Case of Robert Garbutt, æt. 21. (See Guy's Hospital Reports, vol. vii. page 175.)
† See, again, Museum Specimens.

purgative is thought to be only healthy. A spontaneous diarrhoea, removing from the blood the very cause which induced it, does not proceed from mere irritable bowel, though it recur twice a week; and an issue, removing so much from the system, and facilitating, by so much, the natural depurations, has the peculiar office of acting instead of any weak organ, and more copiously, perhaps, than such would, after every exposure or excess, &c. To observe and reflect with advantage requires a broad line kept between what is certain and what is doubtful or fanciful. It may much assist the study of counter-irritation, first, to separate the humoral action from the nervous; and secondly, the quantitative effect from the specific and the variable as relates to the fluids only.

It does not require a Hunter to assert (as Hunter conformed to do) that disordered dentition produced contraction of the fingers and toes; but we conceive more than a Hunter would be required to prove it. Our conclusion is, that we know not how little value to set upon such inferences. We know that a burnt cheek, or an abscess in the jaw, produces no such consequences.

An author in some esteem makes the following reflection:—"Though worms by many people are reckoned one of the principal sources of children's complaints, yet I cannot help thinking, that worm cases more rarely occur than is commonly imagined; for I am very well assured that the common symptoms of worms, such as picking the nose, grinding the teeth in the sleep, starting and calling out while asleep, sleeping with the eyes half-open, a wan complexion, a stinking breath, pains in the stomach and bowels, a want of appetite, or, on the contrary, a perpetual craving for food, a depraved appetite, &c.,—I say I am well assured that all these symptoms are frequently produced from a foulness of the primæ viæ when there are no worms in the case. I have good reason to say so, because I have had numbers of children with the above symptoms under my care, who, by the use of proper medicines for cleansing the bowels, &c. have got rid of them all, without ever having been observed to void one single worm, though while their purging medicines were operating the stools were carefully inspected. Nay, I may venture to say,

that of the whole number of children brought to the dispensary, who from the apparent symptoms are supposed to be troubled with worms, there is not one in ten that has ever voided any, nor do any make their appearance during the whole time of the cure*." We are glad to find some authority opposed to the fancy of worms. We hope that it will not be very difficult for our readers to explain each of the symptoms referred to worms by recurring to the general state of the body, which of course affects, and is affected by the primæ viæ, as it is influenced by cold or heat at the surface, or cheerfulness in the mind, by secretion, depuration, loss or repletion.

It is common enough to speak of local irritation keeping up general disturbance, as fever, hectic, tetanus, convulsions, and the like, but we should endeavour to dissect the substance of these opinions. Pain produces its effects, anxiety likewise, and any material discharge will be an additional distress to the whole system.

Is it wonderful that with the deteriorated body the opening of a psoas abscess, of an hydatid or ovarian cyst, of a bursa or a joint, should be the starting-point of fresh and terrible morbid changes. The mere defect of reparative acts is a daily augmenting source of mischief. The tardiness of repair natural to some tissues is another evil. What are the rigor and fever of catheterism but evidences of the last impulses of the overturning balance?

Sir B. Brodie, perhaps rather hastily, expresses the following opinion:—"The heart sympathises with the local irritation (of stricture or catheterism), the pulse is hard and frequent, the face flushed, the skin hot, and the tongue is coated with a white fur." Now we know that this train of symptoms belongs only to a disordered body, and cannot be produced as a general result by the supposed causes. It is a very different mode of viewing the facts, to observe that the smallest cause may unsettle the balance when delicately hung, or make the weak body tremble; and that even the greatest sudden causes are hardly equal to any similar effects when all is strung for resistance.

Mr. Hunter, for once too ready, we

* Vide London Med. Review, vol. i. p. 237.

think, to take up the floating doctrine of his school, did not scruple to impute gout in the stomach to sympathy of that organ with cold feet, but we hardly now doubt that the humoral circumstances must be first ripe for gout when something less than cold feet may decide the event, as probably a very little thing directs its locality. A writer in the *Medico-Chirurgical Transactions* imputes hæmoptysis to worms in the intestines: how are we to admit that any but local physical injuries or capillary nutritions can cause bleeding?

The *contiguous sympathy* of Hunter is resolvable into a very simple process of capillary function. A spot being inflamed, good nutrition repairs it; and thus "*resolution*" precludes the manifestation of contiguous sympathy. On the other hand, when nutrition is perverted, the inflammation persists; and the same disordered nutrition prevailing, the adjacent capillaries take on the same kind of inflammatory action as occurred in the initiative spot. It is easy to see that all parts being defectively nourished alike, the capillary next to the disease being also in addition locally disturbed, should be most ready to fail—that it is, as it were, attacked in front as well as unsupported in the rear. Besides defective supply there is obstruction or too easy exit for its contents. Say only that increased heat or chemical activity is near. It is doubtless true that in different states of the fluids different tissues are the most prone to disorder and disorganization; but it is equally certain that different kinds of inflammation do not invade the same body at once. There is watery, or purulent, or fibrinous inflammation in several organs at once. These three never affect the same body at once—*diffusing inflammation*, "*contiguous sympathetic inflammation*," is only the persistence of the first general state, keeping up and extending the first mode of local action. Wide-spread inflammation subsiding is the result of a salutary change in the blood, operating first where the inflammatory deterioration has been least, and repairing gradually the more disturbed parts. Here the repairing blood invades the diseased capillaries in front and in flank as the little tubes (with the tissues they inhabit) become one by one re-

paired, and contract and give up, or spare, all surplus of supplies to their more needy neighbours.

Contiguous sympathy is therefore not a nervous consent of parts, but a humoral action on the capillaries and solids. Two joints, several bones, or all the serous membranes, take on one kind of inflammation together: even gout or erysipelas may invade external and internal parts together: but there is a substantial reason why copious solid effusions should often be confined to one part: it is obvious that diffused phlegmon of a limb must tend to preclude for the time the like changes in a lung or elsewhere, though a febrile or even an inflammatory state prevail in the whole body.

A pustule may be very little more than an incomplete ulceration or atrophy: where pustules or excoriation appear around a sore or under a poultice or strapping, we see, first, constitutional defect; secondly local irritation or difficulty; and thirdly, perhaps some contiguous sympathy or capillary derangement extending continuously from a sore. All these may concur, but which is the efficient source of all? and what but the blood repairs all?

Local disease is a cause of simple irritation when it acts by causing pressure or extension, or by removing them. A tumor exemplifies the first effects, and ulcer the last.

Gout in the foot may remain long nearly stationary, while a febrile state of body is arresting nutrition and leading to relief by gradual depurations throughout the system.

Fresh general deteriorating causes make the gouty action suddenly spread, or seize the meninges. There are modern surmises that some such element as lithate of soda in the blood is the causative specific of gouty inflammation. We would, however, look more circumspectly at the whole phenomena. We see perverted nutrition, tumefaction, softening, thickening of fibrous tissues, and sensitive tissues in particular, together with a mere modification of common fever; and as all the functions have been previously disordered, we know that they will subsequently return to an easy and happy measure of activity. It is altogether unreasonable to suppose that all the several disturbances of gout should depend on a single and simple chemical compound.

We feel that apology is needed for the manner in which our subject has been here treated*.

To show that diseases are not simple mysteries is comparatively easy: to demonstrate any one disease as a series of certain causes, is scarcely yet practicable. If we have done anything towards removing error, or to introduce the right method of tracing the events and complications of disease, we may hope to be excused for many deficiencies in our attempts to define irritation.

If there be specific sets of causes of catarrh, phlegmon, fever, dropsy, struma, and cancer, surely the method we propose may be expected to bring us nearer to the right knowledge and management of them; and so much we yet hope to establish satisfactorily.

36, Bedford Square,
May, 1844.

REPORT
ON THE
ROYAL MATERNITY CHARITY.

By F. H. RAMSBOTHAM, M.D.

(For the London Medical Gazette.)

[Continued from p. 331.]

DURING the year 1838, there were delivered in the Eastern District of the Royal Maternity Charity, under the superintendence of Dr. F. H. Ramsbotham,—

2136 women—Of which cases,

25 were twins—about one in every 85½ cases: of these in 11 cases both heads presented; in 9 the presentations were head and breech, or some part of the inferior extremities; and in 5 both were breech or inferior extremities. The children in 5 cases were both boys; in 8 both girls; and in 12 of different sexes.

1115 were males.

1046 were females.

2087 were presentations of some part of the head; of which 7 were face presentations—about one in every 310 births.

68 were presentations of the breech, or some part of the inferior extremities

—being about 1 in every 32 births; of these 19 were twins.

6 were transverse presentations; all of the shoulder or some part of the upper extremities—about one in every 360 births; all these children were at full time, and delivered by "turning;" three of them were born dead.

In 1 the placenta was implanted entirely over the os uteri; the breech was presenting above; the feet were brought down, and the woman delivered without a great loss of blood: she did well. The child was still-born.

6 were complicated with alarming hæmorrhage before delivery, *not* the result of placental presentation—one in every 356 cases. In one case the flooding was occasioned by a severe fall which the woman met with; in another the funis prolapsed: in all the hæmorrhage was stayed or much diminished by the membranes being ruptured. All the children were expelled naturally; three of them still. All the women recovered.

In 11 cases the placenta was retained within the uterus, either by atony, or irregular contraction of the uterine fibres, or by morbid adhesion between the uterine and placental surfaces, requiring the introduction of the hand for its removal—about 1 in every 194 cases. With all there was more or less of hæmorrhage. Two of the women died; one in two hours after the removal, from the hæmorrhage; the other in 10 days, from hysteritis.

4 were complicated with alarming hæmorrhage after the placenta was born—one in every 534 cases. One woman died; it was a case of twins; the labour was very rapid; both children were expelled before the midwife arrived: an officious neighbour who was present immediately pulled away the placenta, and when the midwife got there the patient was dying.

3 were delivered by the forceps—1 in every 712 cases; 2 of these were first children; one was the woman's 12th; the uterus acted feebly from the commencement of labour: 2 were born living; the latter dead and putrid.

In 1 premature labour was induced artificially at 7½ months by perforating the membranes; the woman had a small pelvis, and the same operation had been performed for her frequently before; the child was born living 52 hours after, but only survived an hour.

* Various matters in connection and corroboration, and even in continuation of our views, may be found in papers of this journal, Guy's Hospital Reports, &c. communicated during the last few years.—T. W. K.

2 were complicated with rupture of the uterus—1 in every 1068 cases: one was the woman's 10th child; she always had had lingering labours, her pelvis being distorted at the brim; the accident occurred 8 hours after the membranes had broken; the head presented; the pains had never been strong, and the rent was not attended with any tearing sensation; it was horizontal in the anterior part of the cervix. When I arrived, both the child and placenta had escaped into the abdomen, from which cavity I removed them, delivering *per vias naturales*, by the feet: the child was dead: the woman rallied somewhat after delivery, but died in 24 hours. The other patient died in 40 minutes after delivery. It was her 8th child, and a head presentation.

9 women died either from puerperal causes, or within the puerperal month—one in every 237½ cases.

2076 children were born alive.

85 children were born still—about 1 in every 25½ births.

Of the Deaths,

1 was from hæmorrhage speedily after the birth of twins, in consequence of a neighbour officiously extracting the placenta, during the midwife's absence.

1 two hours after the removal of an adherent placenta, from hæmorrhage,

1 from hysteritis 10 days after the removal of an adherent placenta.

1 from "collapse" five hours after delivery of a dead child; there was no flooding: I suspected a disease of the heart.

2 from ruptured uterus; one 40 minutes; the other 24 hours after delivery.

1 from puerperal mania a month after delivery.

2 from common fever; one 7, the other 10, days after delivery.

Of the still-born children,

19 were premature.

12 were putrid, at full time, or nearly so.

14 were presentations of the breech or some part of the lower extremities, at full time or nearly so.

3 were transverse presentations.

1 was delivered by the forceps; it was putrid.

4 under very lingering labour.

2 under ruptured uterus.

2 under a face presentation.

863.—xxxiv.

1 under a placental presentation.

2 after violent accidental hæmorrhage.

With 5 the funis prolapsed by the side of the head.

With 7 the funis prolapsed by the side of the breech; 1 was acephalous.

12 were at full time, not putrid, nor delivered by art.

TWO CASES OF UNUSUAL DISLOCATION.

To the Editor of the Medical Gazette.

SIR,

I beg to submit the following brief statements of two unusual kinds of dislocation, and shall feel obliged if you will insert them in your journal.

Your obedient servant,
J. C. SPENDER.

Gay Street, Bath,
May 12, 1844.

1. *Dislocation of the sternal extremity of the clavicle backwards.*—Some time ago, I was requested to visit a gentleman, residing about three miles from Bath, who had received an injury from a fall. He was riding at rather a rapid pace, when his horse fell, and threw him off; and the animal, in attempting to rise, placed one of his forefeet on the right clavicle, whilst the gentleman was still lying on his back. Considerable uneasiness was immediately experienced by the patient, with a sensation of something passing into the upper part of the right side of his chest. On examination, the right clavicle at its sternal articulation was found completely dislocated backwards, leaving a vacant space at its junction with the sternum. By placing a wedge-like compress of sufficient thickness in the axilla, and forcibly drawing the humerus outwards and backwards, the clavicle approached its natural situation; and tight bandages of flannel were employed to keep the arm in that position. Some uneasiness was felt during the night—more, however, from the bandages than from the injury—but the patient became accustomed to the pressure, and the applications were not removed for several days. This plan was pursued for a sufficient time, and the bone is now perfectly fixed in its proper place, so that there is no more depression at present existing than in the articulation of the opposite side.

2 B

2. *Dislocation of the carpal extremity of the ulna inwards.*—A lady, at the latter end of last January, was seized early in the morning with giddiness, and fell forwards. On being lifted up, the left arm was found useless, and the right wrist stiff and painful; but ignorant of the serious nature of the disease, I was not called to see her until 12 o'clock. At this time the wrist was greatly swollen, so as to render it difficult to determine the precise character of the injury. The fingers were rather bent, but not forcibly so, admitting of tolerable motion with little difficulty. The distance from the elbow to the apex of the fingers corresponded with the length of the opposite forearm, which seemed to prove that there was no dislocation in the ordinary way either backwards or forwards; and although there was great tumefaction, yet it was of an uniform kind, not abrupt, as if produced by the displacement, still less by the overlapping of the carpus on the forearm. The thumb was not quite in a proper line with the radius, but slightly inclined inwards; not, however, sufficiently so to convey the impression of an usual dislocation of the lateral kind. The ulna at its articulation with the cuneiform bone was not perceived, in consequence of the swelling, but the bone higher up the arm seemed to be in a proper line with the little finger; beyond this, the swelling was so great as to render it impossible for me to determine the exact nature of the accident. Leeches, cold lotion, and the other common remedies to lessen inflammation, were employed; and on the following day, the same obscurity existing from the same cause, the limb was supported on a splint, with the view of straitening the parts in their natural position, whatever the injury might ultimately prove to be. These means were continued for a few days, and when the swelling was sufficiently removed to make the discovery, the ulna was found to have sunk down from its attachment with the carpus, and to be pressing on the flexor tendon ulnaris. I then employed two firm splints, interposing a compress on the depressed end of the ulna with the design of raising the bone to its proper position, but the application produced so much pain that the splints were removed soon after I left the house. As it appeared impossible to bear the requisite pressure from the two splints, a long single flat one was

selected, extending from the elbow to the fingers, and resting the forearm on its surface: the radius and carpus were bound down so as to approximate them to the depressed ulna; but the tapes had frequently to be removed, in consequence of the pain they excited. This plan was pursued for about three weeks, when the fingers, which had been kept in an extended position, were stiffened, from the effects of inflammation propagated from the wrist. This threatened also to be of a rheumatic description, as the lady, previously to the accident, had been suffering from chronic rheumatism of the right lower extremity. I then thought it better to compromise matters, and rather than permit the fingers to become stiff, and perhaps useless, to allow them to be moved, even at the risk of perpetuating some deformity at the wrist-joint; supporting the depressed ulna with a piece of soap plaster or thick leather, and using the splint only at night. The swelling gradually lessened, and allowed me more perfectly to determine the character of the injury, which I found to consist in a very marked and unusual displacement of the articulating end of the ulna, whilst the carpus, having lost the support of this bone, and still attached to the radius, gave an obliquely distorted character to the hand at the joint. By gradually and steadily using the hand there is a very tolerable and improving motion in the fingers, enabling the patient to write, and to feed herself; there are also ample powers of rotation at the wrist; but there is yet inability to bend the fingers close to the palm, and an unnatural appearance at the joint.

CONTRIBUTIONS
TO THE
PHYSIOLOGY OF THE HUMAN
OVARY.

BY CHARLES RITCHIE, M.D. Glasgow.

[Concluded from p. 268.]

25. The simultaneous development in the ovaries of two corpora rubra (20) was not met with in the present series of observations—a circumstance which may be attributed, however, to the comparatively limited nature of the latter, the general results of which, in respect to the ovaries of recently impregnated females, may be thus stated.

Appearance in Ovaries of,

|---|--|

26. There was no evidence furnished by any part of the investigation that granular matter was ever secreted around an unruptured Graafian follicle. A few of the cephaloid bodies in the pregnant female, instead of containing a coagulum, or being either empty or having their walls agglutinated together, were distended by the exudation from their inner surfaces of a transparent fluid, of a reddish, of a green, or of a yellow colour, the minute foramina by which they had been originally emptied of their ova and granular fluid having become obstructed, either by

the contraction on them of the pulpy structure of one variety (19 A), or by the elasticity of the other (19 B), and an appearance produced which, unless for the discovery of the capillary-sized openings by which they had been perforated, might have been mistaken for Graafian vesicles still undischarged, and having a deposit of granular matter covering their coats. (P. II., S. I., 4, 5; S. II., 2; S. VI., 8.)

27. A nipples or cumulated protuberance of the surface of the ovaries over a granular cyst; crateriform openings on the apices of the latter,

with vascular edges; and serrated "internal cicatrices," as they have been termed, traversing the interior of the cephaloid bodies; and blood-vessels ramifying on their granular matter, were not peculiar, as has been asserted, to the gravid female. (P. I., S. II.; P. II., S. VII. *passim*.)

28. Immediately on the arrest, and during the suspension, of menstruation, by pregnancy, lactation, disease, or old age, the Graafian vesicles were found less vascular, of greater tenuity, and of smaller size, than their normal structure in menstrual life, and to rise to the circumference of the glands, and to be eliminated by very superficial and capillary-sized punctulated lesions of the surface of the ovary, precisely as, during infancy and childhood, the linear or angular cicatrices of menstruation, becoming at the same time gradually filled up or erased. (P. I., S. III. IV. V.; P. II., S. I. II. III. IV. V. VI. VIII. *passim*, S. IX., 4.)

29. The coexistence of this modification of the ovisacs with the presence of cerebriform or of white bodies in the ovaries, was not peculiar to the gravid state, and could not, therefore, be relied on, unconditionally, as a proof of pregnancy (P. I., S. III., 2, 3; IV., 1, 3; V., 2); but its weight, as evidence of the earlier months of that condition, might be esteemed considerable when the corpora cephaloidea were large, massive, highly organized, and associated with similar bodies of a less perfect kind and smaller size, linear cicatrices, and other marks in the ovaries of recent menstruation, and, also, with the existence in the uterus of a deep mahogany-coloured stain, from the late adherence of the ovum (P. II., S. I., 4, 5, 6, 7). And the same estimate of its value, as a proof of a not distant parturition at the full term, was warrantable when the corpora albida were perfect; the mammae, abdomen, and thighs, indented with lineæ albicantes; the uterus bulky, discoloured, and flaccid, its labia fissured, and the spermatic or hypogastric veins occupied by coagula. (P. II., S. II., 2, 4; S. III., 1, 4; S. V., 4, 5; S. VI., 4, 7.)

30. The obliteration of the cicatrices peculiar to menstruation, the presence of miliary ovisacs in the ovaries, and their appearance beneath the peritoneal coat as small copper-coloured spots, along with others of a yet more minute

size, which had penetrated the substance of this membrane, and which did not require more than its thickness for their entire inclusion, together with the protrusion of some of these, often with extremely attenuated coats, in the form of very minute vesicles at the surface of the ovary, or along with puncta, or with a raw, blistered, or abraded appearance, occasioned by their recent rupture; and the existence at the same time, in either ovary, of a cerebriform body (19 B), having the granular matter exterior to the two inner layers of the ovisac, or of a mottled, yellowish red, or of a roseate coloured or red fibrous body (20), was a combination of circumstances which was met with exclusively during pregnancy, or within four months after delivery at the natural term. (P. II., S. I., 10; S. II., 1, 3, 5; S. III., 2; S. V., 1, 3.)

31. The changes in the character and mode of the production and discharge of the Graafian vesicles which follow suppressed menstruation, from whatever cause the latter proceeds, was not seen to occur earlier (P. I., S. II., 8; P. II., S. I., 5) than two months after the last menstrual flow; and previous to the expiry of this period, therefore, there were, in such cases at least as presented only the cephaloid bodies (19 A), no indications by which the fact of pregnancy could be determined (P. II., S. I., 1, 2) irrespective of the discovery of the ovum, and the greater organization of the deciduous fungiform villousities which are thrown out in the uterine cavity at every menstruation, and which, in such cases, suggest the idea of their being the rudimentary spiral arterial coils and horizontal sinuses of the membranous decidua.

32. In some cases of newly-established menstruation (P. I., S. II., 3), and also of amenorrhœa of short standing (P. I., S. IV., 1), an aggregate of phenomena was met with similar to that seen in the earlier months of gravidity, consisting of a diminution of the size of the ovarian follicles, the presence of well-developed cephaloid bodies, the remains of linear cicatrices, and a smooth appearance of the ovaries, studded, also, with copper-coloured macules, minute vesicles, and porous openings, and united, in the lately menstruating female, to a vascular, congested, and ecchylosed state of the

internal surface of the uterus; and in such cases, also, it is impossible to distinguish the state from that of those examples of early pregnancy (P. II., S. I., 2, 3, 5a, 6, 7), in which the corpora cephaloidea are of the construction (19. A) met with in the virgin ovary, except by a reference to the history of the individual, and the size and other conditions of the uterus.

33. While the compatibility of pregnancy with the presence in the ovaries of cephaloid bodies, having a delicate inner layer similar to that seen in the same bodies in the unimpregnated female, is undoubted (compare P. I., S. II., P. II., S. VII. with P. II., S. I.); the inner layer of ruptured ovisacs was sometimes found either (P. II., S. VII., 11, 12) in process of thickening, or (P. I., S. IV., 3, 6) already converted into a hard cyst, in circumstances where the appearance had no connexion with pregnancy; but on these occasions the hypertrophy of the inner layer was not accompanied by any deposition around it of granular or cerebriform matter; and in no instance was the union of hypertrophy of the inner coat of the discharged follicle, and the formation on it of cephaloid tissue, met with, whether the former was gathered up (P. II., S. I., 4, 5, 8, 11b) within the latter, as an insulated pellet or a thickened vesicle, or was extended out on it (P. II., S. I., 6a, 9, 10, 11a) as an open cavity, unless during uterogestation, and that also frequently in its earlier months; while the latter months of the same condition, and a period of four months after natural parturition, although obtaining sometimes without such appearance, were uniformly indicated when a corpus rubrum was present (P. II., S. I., II., III., IV., V. passim), the red body so found being always a conversion of one or other of the varieties of corpora cephaloidea (19. A, and B).

34. The only special indication which distinguished the ovaries of lactating women delivered at longer periods than four months after the natural term, was the unusual prevalence in them, coexistently with the general characteristics already noted, of corpora alba, — a circumstance dependent, probably, as is also the diminished size and organization of the unruptured vesicles in the same cases, on the lowered vascular activity of the uterine system

during lactation. Compare P. I., S. II., and P. II., S. VII., with P. II., S. VI. See also P. II., S. II., III., IV., V. for the fact of the predominance of white bodies generally in the lactating as compared with the menstrual state.

35. The ovarian condition which most resembles what is here stated as occurring during lactation is that met with in amenorrhœa from disease, and as this, whether temporary and occasional, or even protracted, may obtain, contrary to the opinion of some, along with a plump state of both glands, and a profusion of Graafian vesicles, some of them of good size, and, in recent cases, of considerable density, nothing absolute can be founded on the fact of white bodies being discovered in the ovaries, independently of the other circumstances of the case, beyond a mere probability that it may have been connected with the puerperal condition, a probability which may safely be believed, however, to increase with the number of these bodies, and with the freedom from atrophy of the uterus and its appendages (P. I., S. III., IV., V.; P. II., S. VIII. IX. passim).

36. Graafian follicles of some size were found in the ovaries for fifteen, and white bodies for twenty years after the critical age (P. I., S. V., 2; P. II., S. IX., 3a, 5), and the discharge of attenuated minute vesicles, apparently simple cells, from the surface of these glands, appeared to terminate only with life (P. II., S. IX.)

37. No relation was found to exist between the number of corpora alba discovered in the ovaries after death and that of the previous pregnancies; nor was there any specific distinction in the ovaries of women who had borne children as compared with those of females who had not been gravid.

38. Numerous examples of amenorrhœa in its varied forms as connected with slight functional indisposition, pregnancy, lactation, organic disease, and old age, were observed, in which the ovaries remained of good size, and even in some instances (P. II. S. VI. 10) were larger than natural. Passim.

39. Cases in which the ovaries were more or less crowded by well-developed Graafian vesicles coetaneously with the non-establishment of menstruation at puberty (P. I., S. I. 4, 6, 7, 8, 9, 10), and with its suspension by chlorosis (P. I., S. III. 1, 2, 3), and by pregnancy at

the sixth week (P. II. S. I. 2), at the third (idem, 4) month, at the fourth (idem, 6 ?) month, at the seventh (idem, 7, 8) month, and by lactation at the first (S. II. I. 3), fourth (S. V. I. 4), fifth (S. VI. I.), and sixth months (S. VI. I. 2, 4), were noticed.

40. Instances of one or more menstruations taking place in succession in the same female, without the corresponding rupture of a Graafian follicle, were often seen (P. I., S. II., 2, 3, 5, 7, 9, S. III., 2, 3, P. II., S. VII., 1, 3, 4, 5, 6, 7, 9, 10, 11, 12); and in some cases (P. II., S. VII., 1, 7) it was demonstrable that, although the ovaries were occupied by very vascular and distended vesicles, and menstruation was normal, no lesion of a follicle had occurred even after several months; while in one woman (P. I., S. II., 1) no less than eight, and in another (idem, 2) the strong probability of at least three times that number of consecutive menstruations having elapsed without the occurrence of that kind of rupture said to be essential to menstruation, was capable of proof; while in a third (idem, 3) there were no more than five of the large cicatrices and other indications described by some as following every successive menstruation, to set against at least three years of the probable subsistence of this function; and in no case was it found that there was any approach to an accurate relation between the number of foramina or of cicatrices observed in the ovaries, and that of the presumed menstruations previously undergone by the woman.

41. The uterine appendages were not on every occasion found remarkably injected with blood during or near to the time of the catamenial flow, and with one exception, in which the mucus of the tubes was of a red colour, most probably from regurgitation of the effused blood of the uterine cavity, the ovaries and tubes were even less turgid, in the few cases of actually existent menstruation which are recorded, than on some other occasions (P. I., S. II., 2, P. II., S. VII., 1, 6).

42. In some of the cases of the present series, as in others recorded by different observers, the vagina was found very red and vascular during menstruation (P. II., S. VII., I.).

43. The miliary sized vesicles obtaining in the different forms of suppressed menstruation, instead of bursting, and

being discharged when they reached the external surface of the ovary, which was the rule, were seen sometimes to traverse a portion of the broad ligament, and occasionally to become solidified in this situation (P. I., S. III. 3, S. IV. 3, 6, 7, P. II., S. II., 5, S. VIII., 1, 5, S. IX., 4, 5).

44. A similar extrusion of corpora albida from the ovary to the broad ligament was also met with (P. I., S. IV., 6), and in both classes of cases a slender pedicular connexion of the bodies with the ovaries was in a few instances observable (P. II., S. IX., 5).

45. In most of the examples of extruded vesicles here (43, 44) referred to, the Fallopian tubes were impervious (P. I., S. IV., 6, P. II., S. II., 5, S. VIII., 4, S. IX., 5), and in such cases the secretion by the ovaries of numerous transparent minute vesicles with fragile non-elastic coats, and the discharge of those, as appeared, into the abdomen, seemed to continue irrespective of the tubal obstruction*.

46. The Fallopian tubes of women at seventy years of age were found patent (P. II., S. IX., 6).

47. Ovisacs containing altered blood or having their coats dyed black (corpora nigra), or yellow (corpora lutea), may occur independently of menstruation, and were, exclusive of the effusion of lymph from the extremities of the tubes and the exterior of the ovaries, which appeared to have a similar origin, the only ovarian changes which could be suspected to have any

* This fact is illustrated by many of the cases already recorded, but in the following, which was omitted in its proper place, it is seen in connexion with the apparent persistence for a series of years without rupture of the vesicles peculiar to middle life (P. II., S. IX., 3: —, above 60, the mother of a family). Both tubes impervious by adhesions of their fimbriated extremities, in which, and under the peritoneum covering the posterior aspect of the tubes, were numerous vascular vesicles, with dense elastic coats, and of about the size of coriander seed; their contents when punctured escaping with a slight gash. On the ovaries were noticed another description of vesicles, so small as scarcely to be observed without a magnifier, some of them still imbedded in the surface of the gland, like eyes, and others protruding beyond it nearly with their whole circumference. They were quite pale and transparent, and very thin and non-elastic in their texture, and adjoining some of them were slight indentations which appeared to proceed from the recent rupture of some of their number. Interior of glands contained two well-formed corpora albida, and consisted of a membranous pulp, covered with extremely small sized, transparent, vesicular points, or simple cells, similar to those on the surface.

connexion with venereal orgasm (P. I., 8. I., 7, 9, S. IV., 4, 5, P. II., S. III., 4, 8. IV., 1, 3, S. V., 1, 2, 3, S. VIII., 1, 4, 5).

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

Illustrations of the Theory and Practice of Ventilation; with Remarks on Warming, Lighting, &c. By D. B. REID, M.D. F.R.S.E. &c. &c.

To judge of the way in which we are so commonly treated at our promiscuous assemblies, at our dinner and evening parties, &c., it might be imagined that the persuasion on the part of our host and hostess was, that whilst we could not live for three minutes without meat or drink, we could do very well for a couple of hours or so without air. As for the entertainment we receive in the rooms, halls, theatres, and other places of public meeting and resort, it is generally pretty obvious that neither meat nor drink, nor atmospheric air, is contemplated as among the things necessary to man's existence then and there. We do not know who had the honour of making the discovery, in these latter days, of the imperative necessity of air to the life of man; we remember, however, that the first book we read on the means of supplying so much of this vital fluid as might be necessary was that of Mr. Thomas Tredgold, a man who was highly prized by his friends, and whose early death was sincerely lamented by all who knew him. This work was on the Warming and Ventilating of Public Buildings; and we remember that the way in which the matter was handled impressed us very favourably in regard to Mr. Tredgold's abilities both as an engineer and a writer. The next tractate that we perused on the subject, which has always been a favourite one with us, was Dr. Neil Arnott's pamphlet, with very nearly the same title as Mr. Tredgold's. This, too, we recollect as pleasant reading; and the pamphlet must have found favour with the public; for a very few months after it appeared no copy was to be had for money in the shops: it has never been reprinted.

The excellent work of Dr. Reid, the title of which stands above, has but just appeared, to ease us of the regret we have always felt that there was no readily accessible and adequate means of information for the public upon the really momentous subject of ventilation. Dr. Reid's work supplies every thing that seemed most desirable; it is a comprehensive review of the entire subject, not only of ventilating, but also of warming and lighting, our houses and places of public assembly; and farther, and this is matter of great moment in many circumstances, of so constructing rooms, halls, &c., as that a speaker in one part shall be heard in every other part. The subjects of this work of course imply familiar acquaintance with natural philosophy and chemistry in order to their elucidation: in Dr. Reid they have met with more: a member of the medical profession, he is moreover an excellent physiologist, and farther shews himself conversant with one of the very highest branches of the art medical—hygiène—the means necessary to the health and life of man, and their application; in one word, no one could have been found more competent to the task he has undertaken than Dr. Reid; none certainly could have performed his duty in better taste, or with a more comprehensive grasp of the entire subject.

After an introduction, in which Dr. Reid exposes the constitution of our atmosphere, and the chemistry of respiration, he places in brief but lucid review before us the vast amount of mischief that has befallen mankind from ignorance of the imperative necessity of having adequate supplies of fresh air. One man consuming ten cubic feet of air per minute, which he does, will have used, during a life of fifty years, nearly 900 tons of air! The inhabitants of London, taking them at two millions, use up 359,000,000 tons of air annually, or nearly one million of tons per diem! Suppose ten persons seated in a room twelve feet square every way, they would exhaust the air of the whole of its oxygen in about fifteen hours and a half; but as the air is poisonous to the lungs long before the whole of its vital element is consumed—as even the air that has been breathed once is no longer fit to be breathed again—in order to furnish

thirteen persons with ten cubic feet of air per minute, the atmosphere of the room would require to be completely changed every seventeen minutes, and such a change could not be effected by the ingress and egress of air flowing at the rate of one hundred feet per minute, through apertures of less than about one foot square. This will give the reader some idea of the supply of air that is necessary to healthful existence, and enable him to judge of the circumstances in which he is placed when he is shut up for a succession of hours in a small chamber, or even in a large one, with a number of other persons, and no means are taken to furnish him with the renovated atmosphere that is altogether necessary to respiration and the manifestation of vital phenomena; for that it is so, that his life hangs primarily on his respiration, is made manifest by the fact, that the supply of air interrupted for no longer an interval than three or four minutes, all vital manifestation ceases; the heart no longer beats, the brain no longer feels, nor wills, nor thinks—the man is dead; and he has sustained no injury; nothing has been added to, nothing has been subtracted from, his body; the ingress and egress of some ten or twelve cubical inches of air to and from his lungs have alone been interrupted, and this puts an end to him.

It is indeed high time that men should act as if they really believed a supply of fresh air necessary to them—an abstract or theoretical admission of the fact ought no longer to be received; let those who have houses to build, or who have the control of houses that are about to be built, look to it. Human life in the upper ranks of society, once the age of 20 is passed, is worth at least forty years' purchase; in the labouring class it is not worth thirty years; the difference is, in very considerable part at least, due to the different atmospheres which the rich and the poor man breathes habitually. In his second Chapter, Dr. Reid treats this part of his subject well and forcibly, and shows what room for improvement there is still in the dwellings of all classes of society. He shows upon what the *soporific* qualities of certain rooms depends—it is nothing but insufficient ventilation. No bad air

escaping above the level of the fireplace, the upper part of such apartments is contaminated by perhaps four or six argand-burners, or some dozens of candles, to say nothing of the breath of the assembled company. "The dwellings of the extremely poor," again—and Dr. Reid's language here is so appropriate that we make it a duty to quote it—"present scenes of misery, desolation, and woe, which it is afflicting to witness, where the sensibilities are not hardened against the sufferings of humanity. They must be seen to be understood, and to draw out that amount of individual sympathy which they imperiously demand in a civilized and Christian community. The station of this country in arts, literature, and science, is acknowledged throughout the globe, as well as its naval, its military, and commercial power, and latterly its exertions against the slave-trade have given a noble example in the cause of humanity, and soften the recollections of former times. But the regeneration of its own population, or rather the placing of them in that condition which the progress of religion and philanthropy demands, is perhaps a task of more moral grandeur, and of still more difficult execution, than any other which it has attempted."

Here the Doctor gives a sketch of a room of one of the poorer classes of houses in Edinburgh, such "as he was in the habit of visiting when a student of medicine, 24 years ago."

"The sunk floor, soft, unpared, and unequal, gave out a damp and unwholesome smell; the patients breathed an atmosphere loaded with smoke, except where proximity to the door and window produced local and offensive draughts, and the unhappy children were grouped around a wretched fire, where it was difficult to say whether they suffered more from hunger or cold. Three beds are not shewn in the sketch, that the general disposition of that which has been described may be better understood. At night or morning, from ten to twenty were usually around the fire; each family of four or five had a bed; and those who could not get a place in the bed rested wherever they could lie down. In another place, I have seen five beds occupied, each with one or more sick persons, and no one to attend to their wants, or those of the

infant children exposed in the midst of severe and appalling misery."

The *philosopher* and *naturalist*, it is obvious, are here run away with by the *man*, and we cite the passage as evidence of Dr. Reid's good and kindly heart—but philosophy and medicine have always a humanizing influence. The evil that existed twenty-four years ago, however, exists in unabated force at present, as we shall have occasion to show in our account of Dr. Alison's excellent pamphlet just published "On Fever as connected with Destitution."

Dr. Reid next takes us to the school-room and the church, and shows the ill effects of the vitiated atmospheres of such places—the pædagogues's efforts unavailing, the clergyman's earnestness all ineffectual, under the circumstances in which either is placed. But we cannot spare the space that were necessary to give anything like an adequate idea of the contents of this excellent work, or of elucidating the beautiful spirit in which the several subjects it embraces are discussed. Suffice it to say, that the Second Part is devoted to a consideration of the nature of ventilation, and the means by which it may be effected; Part III., to the mode of producing and communicating warmth, and of lighting; in Part IV., we find the practical application, to the ventilation of the houses of Parliament, of the principles inculcated in the preceding parts. Part V. is a kind of continuation of this 4th part, and embraces miscellaneous illustrations of ventilation; Part VI. considers the ventilation of ships, a very important matter; and Part VII. concludes the work by treating of the ventilation of mines.

Neither pains nor expense have been spared on the publication and illustration of this excellent volume, which, as pleasant and profitable reading, as containing matter that comes home to every man in one way or another, and is ever of vital importance—the whole treated in the very best taste, first, as matter of science, and then of enlightened philanthropy—ought to have a place in the library of every family, and to be made the subject of especial study with every enlightened member of the medical profession.

MEDICAL GAZETTE.

Friday, June 14, 1844.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso." CICCRO.

THE TRUE ENEMIES OF THE MEDICAL PROFESSION.

THERE is a very general feeling in the medical mind that the public are not disposed to estimate us at former high rates—to look upon the medical profession as of that weight and importance which it was once held to have in the community.

This feeling we think in the main well founded; and it seems not very difficult to show the causes out of which it has sprung. Sorry we are to be compelled to say, that we have ourselves to blame in very considerable part, both for the more slender respect in which we are severally held, and for the minor influence that is allowed us as a body. We have been too eager to discover the errors which all as individuals necessarily commit in the practice of a profession so difficult as that of medicine; and more than this—of far more moment than this—we have been of late years incessant in our efforts to expose these errors to the common gaze; to hold them up in their nakedness, and as sins emanating from the ignorance and incapacity of their authors; these being often the very polar stars of our profession. Now the public can form no estimate of the difficulties in the way of judging rightly in points of medicine; but they can all appreciate an error when it is laid open to them, and they are told that the inference ought to have been different from that which was drawn—the procedure other than that which was followed. It was thus that the seeds of suspicion of the very foremost men in all the land, in point of medical and surgical position, were

first sown ; and it was no wonder that these seeds struck root, and by degrees grew up into lusty plants that now overshadow the whole profession. But these plants have proved very upas trees, and we, who of necessity remain under their shadow, have been the first victims of their poisonous breath.

We have lifted the veil, then, from the errors we severally commit, not for the purpose of striving among ourselves to avoid these errors for the future ; we have not spoken of them as incident to our human frailty, as unavoidable in all likelihood, as appertaining to the state of science at the time—No ; they have been sedulously upheld as the errors proceeding from the imbecility of Sir, or Mr., or Dr. this or that, as errors which might readily have been avoided—which ought to have been avoided—which, having been committed, were to take away all confidence in the discrimination and skill of the unfortunate practitioner who committed them in all time to come.

But if the public have the baronets, and knights, and learned doctors of the profession, the men at the very top of the metropolitan tree of practice, satisfactorily demonstrated asses to them, what confidence can they be expected to place in men of lower grade ? The answer is obvious—None ; and then they fling themselves into the arms of homœopathy or hydropathy, or any other opathy, or ology, or ism, that may chance to be in fashion, and that is yet without its quarterly, and monthly, and weekly publication, to expose the errors of its advocates and abettors ! It has been well said, that men are, even at the present day, more ready to pay for astrology than astronomy ; we of the regular profession, however, grounding our science on a study of the laws of life and nature at large, have long ago thrown away our cloaks and defensive armour ; we stand upon our knowledge of and

our trust in God's eternal laws for the good we may be permitted to do in our calling. Homœopaths and hydropathists, sellers of abracadabra and catholicons, cast God, and reason, and science, behind them, and come before the world in the triple mail of ignorance and presumption, with the cloak of deceit drawn over all,—and the public, utterly incompetent to appreciate us with our science, lend their ear to exaggerated promises and large pretensions : the astrologer is preferred to the astronomer.

Again, a gentleman high in rank among us, is held as not having paid that attention to his friend, taken suddenly and seriously ill, which the circumstances of the case seemed to require ; forthwith the tale is blazoned abroad ; like the stream as it flows, the story gathers aggravating characters as it spreads, and finally it is so black and damnatory, that, lumped together, the whole profession are concluded to be monsters utterly heartless and unprincipled. Or otherwise, and thus : Another gentleman, who has achieved a reputation for urbanity, for kindness of heart, and for surgical skill higher, and in so far as practical tact and extensive knowledge are concerned, deservedly higher, than was ever achieved by any man before, is brought into the bear-garden of a common law-court in England, and badgered and baited by one sharp-tongued lawyer after another ; there he uses language figuratively, that is immediately construed and set down literally, and forthwith we are looked upon as butchers, wading to mere manual dexterity through the blood of our fellow creatures—reckless of the mutilations we practise, without a pang for the pain we inflict.—The heart sickens at all this ; but the vulgar gape, and the gentle are confounded, and refuse to give us their hands, and so there is a mark set upon us, and all the good

we do, and have done—our sleepless nights, and anxious days, our generally honourable conduct, our self-sacrifice, our lives shortened in the cause of humanity—all go for nothing. It is thus that we have been blackened as a body, and every thing that could be done to make us infamous has been perpetrated.

Lastly, and strangely enough, the very character of “helper in time of suffering” has been turned against us. There is such a large admixture of charity in all the offices we render in serious cases, that the most selfish and greedy among medical men never think of their reward in the shape of money at the moment of giving their indispensable assistance; the younger member of the profession, in fact, holds himself open to calls upon his services without prospect of fee or reward. Now such is human nature, that service unpaid for is never estimated by the same high standard as that which is, as matter of course and of necessity, handsomely remunerated. Our humanity becomes our enemy; we are held cheap because we cannot as christian men wring money-reward from all and sundry who seek our assistance. The members of the other liberal professions, however, do not work for nothing. Where is the barrister who will undertake a cause without his fee? It may be that there is a poor wretch lying under suspicion that touches his life; if he have not the wherewithal to pay, there are not half a dozen advocates lying in wait, each more eager than the other, to take up his cause and clear him of his difficulties for God’s sake. Where is the clergyman who will marry, or christen, or bury, any member of the community without his dues? Let the man be but poorly, or indisposed, however, and he may go or send to fifty places in the metropolis, and have not only the attendance of a physician or a surgeon of liberal edu-

cation, but all necessary medicines, for the asking; or, being verily ill, or grievously wounded, he has but to get his friends to bear him to a palace, called an hospital, where he will not only be taken in and put to bed, but, if his injury be serious, he will have a surgeon of the highest experience summoned to his aid, whatever the hour of the day or night, and that surgeon will immediately go to his relief; and all this, strange to say, is done for nothing. In this way, appearing ourselves to attach no money value to our services, do the public come to think lightly of them, to look on them as something of little significance, when they are not wanted, as something they have a right to without further consideration, when they are required.

Let us, therefore, be cautious in exposing each other’s errors, simply as such; we can always use them as means of instruction, without hanging up their authors in chains, as they used to hang up the Dutch, and Spanish, and Portuguese murderers and pirates, at Cuckold’s Point, and other significant angles of the Thames—to be pointed at with the finger of detestation, indeed, by the whole Cockney world as it sailed past them to Gravesend, but with the effect of involving, in the Cockney mind, the entire Dutch, and Spanish, and Portuguese nations, in the guilt of these individuals. The Brothers of the Trinity House do not insist on sinking upon the spot the good ship that has discovered a sunken rock or a shoal, as a warning to other navigators; they rather reward the master, and set up a beacon or a light-house as an indication of the danger. So should we use one another in medicine. The valuable means of communication and instruction we possess, in our hebdomadal publications especially, ought to be held as means sacred to the diffusion of new facts, new views, and of knitting the

bonds of good understanding, not only between all classes of the profession, but between the profession and the public at large.

—
THE ST. MARYLEBONE VESTRY
AND THEIR GRATUITOUS MEDICAL
OFFICERS.

WE had hardly penned what precedes, when we were informed of a piece of conduct on the part of the Vestry of St. Marylebone, which admirably illustrates some of the topics we have touched upon. The Vestry, it seems, in its wisdom and economy, conceived that the Infirmary of their parish workhouse was a source of greater expense than it needed to be; that the sick poor cost a great deal of money—more than they were worth, in short; and then the benevolent Vestry set to work to see where the causes of the expenditure lay. These they succeeded in tracing—will it be believed?—to the unpaid physicians and surgeons of the St. Marylebone Infirmary! These gentlemen, said the worthies composing the Vestry, order many very expensive medicines, which are altogether unnecessary for the poor; they, besides, indulge their patients with a diet that is far too good for them, and run us into endless expense for articles which, though they may be in ordinary use for the sick, they are the sick *rich*, not the sick *poor*, who are so indulged. These our gratuitous physicians and surgeons, said they, farther, are men of some pretence, and have extravagant notions; we do not care to have men of liberal education, gentlemen, Fellows of the College of Physicians and College of Surgeons, for attendants on *our* sick poor; we could do very well with a Licentiate of Apothecaries' Company, for that matter; and him, as he is paid by us, we could compel to order salts and senna for all physic, and the ordinary gruel, and soup, and small beer of the workhouse, for all diet, to the saving of at least twenty pounds per annum to our small parish of no more than 150 thousand souls.—And so these learned Thebans—Snout the bellows-maker, Bottom the weaver, Peter Quince, and the rest of them, in conclave assembled—actually passed a resolution to the effect that the services of the physicians and surgeons of the St.

Marylebone Infirmary, although gratuitous, were unnecessary; that the house-surgeon was in himself sufficient to attend all the sick in the Infirmary (they never amount to more than a couple of hundreds or so); and that notification should be given to Drs. Clendinning, and Mayo, and Harrison, and to Messrs. Stafford and Phillips, that their farther services would be dispensed with. This resolution was passed with little or no opposition, and actually stood in force for a week; it only waited for confirmation at the next meeting to be acted on, when all our worthy brethren would have found themselves sent to the right about, with a handsome kick in a certain part that shall be nameless into the bargain, and by way of recompense for their long years of service to the sick-poor of St. Marylebone. Our brethren, however, though they might not have cared much about being relieved of a very laborious duty, did not choose to submit to the indignity which, as they construed it, was attempted to be put upon them; and so, mustering a party in opposition to that of Snout and Co., the resolution was not confirmed, and they remain in office.

It seems that the Vestry of Marylebone parish are extremely anxious to escape the hands of the Poor-Law Commission, which they hope to do by keeping above all things the expenses down to a minimum. We beg Mr. Chadwick to have an eye upon these economists. They mistake the purpose and disposition both of the Commission and its excellent Secretary, if they suppose that they will escape by stinting the sick especially, and the poor under their protection (screw ?) of needful articles of food and medicine. Look after these philanthropists, Mr. Chadwick, we beseech you!

—
REGULATION OF THE MEDICAL
PROFESSION BILL.

THE ANATOMY ACT.

WE are sick of expectation about this bill. Again and again it has stood on the list of parliamentary notices, and again and again it has been put off. It stood for the 30th ultimo, for the 4th inst., and for last night, the 11th; and on each and every occasion it has been deferred. The session is getting far spent, and, we presume, we may now begin to look

for the measure *next year*. Yet Sir James Graham should know that the numerous and highly respectable medical profession are waiting anxiously for his long promised measure, and that to propound and bring it forward would be esteemed a great boon from Land's End to John o' Groat's. Where there is private interest to serve, the motive to action is obviously of a far more powerful nature than that which is *merely* public.

On the evening of the 11th, for example, Mr. Borthwick made occasion to enter into, and the House found leisure to listen to, a most wanton attack upon the ANATOMY ACT, in which he gave full scope to that vulgar love of the horrible and disgusting which we always see associated with ignorance and the purpose of making out a strong case. The purpose by and by appeared: it was to force a Mr. Roberts down the throats of the ministry as the discoverer (discoverer!) of a means of preserving dead bodies sweet and fit for dissection for any length of time, implying the possibility, too, of a single body or so being thereby made to suffice an entire school for the whole of a winter session. Would processes of embalming or pickling suffice us, we are altogether independent of Mr. Roberts. What can he tell us that we do not know already? We can readily preserve a body sweet for several weeks by more than one process, the details of which are familiarly known. But all the preservation and pickling of subjects in the world is useless. The student must have opportunities of examining again and again the parts of the human body in their *most natural state*; and in the progress of his examination of the fabric he necessarily separates the pieces which compose it. What is the primitive and accepted signification of the word anatomy?—*anatomy*—to separate into constituent parts.

There are good points about Mr. Borthwick's speech, nevertheless; had he not had Mr. Roberts behind, at the bottom of his bag, he would have done very well. He assumed it as absolutely necessary to the education of medical men that the practice of anatomy should be liberally carried on; and this being so, that there should be every means taken to secure an ample number of dead bodies. Let him set his face

against Mr. Roberts and his like, who for selfish ends, and to make their *discoveries* (!) available, begin by doing all the mischief in their power. It seems that this person has been agitating against the anatomy act for several seasons past, and that he has actually been the cause wherefore more than one parish and union have refused to assist in making that excellent provision effectual, thereby throwing the teacher and student back upon the degrading and horrible practice of disinterment. And this man comes before parliament and the country seeking reward! The inspectors of anatomy should have the statements made by Sir James Graham and Lord John Russell printed; and they should circulate them to the members of the vestries and guardians of unions along with every application for assistance in connection with anatomy.

We are far from advocating inattention to the feelings and even the fancies of the public in regard to the disposal of the dead. All we know is, that nature treats a dead body with very little ceremony. A few days, often a few hours, and all that was beautiful and loveable in life is a mass from which sense shrinks, too horrible to be contemplated, too noisome to be retained in the eye of day, and that must be burned, or buried, or sunk in the sea fathoms deep, in order that it may not become the cause of pestilence among the living. And if a student do prepare the bones of a member he has been studying, we cannot for our lives see any great harm in the act: he but delays for an indefinite number of years the decomposition that would have been accomplished in a limited time. As we advance in science we seem to see that we are even in some sort bound in conscience to restore, for the use of our successors, the materials which have been stored up in the bodies that have served us during our lives. There is a perpetual round in nature; nothing is lost; decomposition has re-construction as its consequence; death has renewed life; all is harmonious, all is perfect.

THE MODEST AUTHOR.

To the Editor of the Medical Gazette.

SIR,

THE following seems to me too good to be left quietly in the pages of your

contemporary: let me help you to a transcript of it, and a short commentary:—

"I would refer those who wish to prosecute this subject to my work on the Diseases and Derangements of the Nervous System, but especially to my New Memoir, which contains the most lucid and recent view of the whole subject of the physiology and pathology of the true spinal system, and plates which, for skill in the draughtsman (Mr. Simpson, of Stamford), both that of the artist and that of the physician, and for interest in a practical point of view, have not been surpassed. Each plate evolves a principle of physiology or pathology of great interest and value."—*Extract from Practical Observations and Suggestions.* By MARSHALL HALL, M.D. F.R.S. &c.—*The Lancet*, May 18, 1844.

Now, my dear Mr. Editor, I think you will agree with me in saying that you have met with little, whether in matter or manner, that surpasses this. The dullest sense cannot fail to be penetrated by the beautiful modesty of the author, who, in speaking of himself and his own labours, refers those who wish to prosecute a subject, to his works, as containing most lucid views of the whole matter. I wonder that the word "prosecute" was made use of here. Prosecute means to pursue, to follow out, the party's own ingenuity serving him for something. "To learn," or "to be informed upon," would have been the proper term or phrase; for where a subject matter is most lucidly exposed, *i. e.* exhausted, we can only be referred for information as learners to a particular source—just as cattle are referred to a trough when we would have them drink. Referred we are, however, to the "New Memoir" especially, which, as said, "contains the most lucid and recent view of the whole subject of the physiology and pathology of the true spinal system, and plates which, for skill in the draughtsman (Mr. Simpson, of Stamford), both that of the artist and that of the physician, and for interest in a practical point of view, have not been surpassed." I pass by the reiterated proofs of modesty here, to concentrate your admiration upon the style—the New Memoir, which contains the lucid views, and the plates which, for skill in the draughtsman (Mr. Simpson, of Stamford), both that of the artist

and that of the physician, and for practical interest, have not been surpassed! I thought I had a glimpse of Dr. Marshall Hall's meaning here before I set his words down for the second or third time; but on looking at them again I own myself foiled—"Skill in the draughtsman (Mr. Simpson, of Stamford), both that of the artist and that of the physician."—Is it that the skill of the draughtsman is Mr. Simpson's, and the skill of the physician is Dr. Hall's? or is it that the combined skill of the artist and physician is Mr. Simpson's? This would be giving too much to Mr. Simpson, who besides is no physician; and further, Mr. Simpson, the draughtsman, is distinctly indicated. So I must needs conclude that it is the physician, Dr. M. Hall, who exhibits his skill in these unsurpassed plates. But next, I am gruelled with a physician exhibiting his skill upon a plate: "How does you do it, Sairey Gamp, says Mrs. Harris?" Favente Minerva, I think I have it: we have all heard of a clown at a fair exhibiting his skill by dancing a horn-pipe upon a "trencher;" and a trencher is a plate. Can it be that Dr. Marshall Hall has been manifesting himself in any new professional walk? Has the Doctor been seen at any of the recent meetings at Epsom or at Ascot? Let us try again—"Skill in the draughtsman, both that of the artist and that of the physician!" Has Dr. Marshall Hall been taking lessons in dry point? and is the skill he exhibits that of the engraver? The difficulty I have here is, that the physician would then be merged in the mechanic, and there would still be no room for the combination I have invoked to help me in my dilemma. I can make nothing of this point, then, and so proceed to another. "Each plate evolves a principle." Well done the plate, say I! the next plate which Dr. Marshall Hall tries his skill upon will be engendering its like at the least. If a copper or a steel plate, or the imprint from either, can "evolve a principle," I see no difficulty in the way of its begetting a young plate,—do you?

I am yours always,
S. T.

London, June 1844.

[We have the above from an old correspondent; did we see it as likely to be offensive to Dr. M. Hall we should

not insert it. As a *jeu de mots* we believe he will do what we have done—laugh.—ED. GAZ.]

CASE OF INFLAMMATION OF THE SPINAL MARROW.

By DR. BERGMANN, of Coblenz.

A MAN, of 56 years, in the habitual enjoyment of good health, began, without assignable reason, to complain of pain in his left hand, which was much swollen, particularly on the back, as well as the fingers and the wrist, but without any change in the natural colour of the skin; slight pressure occasioned severe pain. No general symptoms; appetite excellent. The repeated application of leeches, and of the blue ointment, soon dissipated the pain. A few days afterwards pain was severely felt in the left arm and shoulder, from whence it extended to the back; and now a general stiffness of the whole body began to be experienced; the patient could only lie down upon his back, and every movement was accompanied with the greatest suffering, referred to the back. By degrees the patient lost the power of moving his arms, and soon the same mobility extended to the legs, which by and by lost all sensibility; they could be pricked with a pin without the patient feeling anything. The lower extremities were also seized with convulsive twitches from time to time, and these were accompanied with severe pain. The feces were passed involuntarily; the bladder had to be emptied by means of the catheter. Pain of a severe burning description was referred to the back. Gradually the body became bent backwards; opisthotonos supervened. During the last three days the brain was also affected; the patient became delirious, and then comatose. The whole disease lasted from the 15th of January to the 5th of February. In the course of the very first days, *decubitus*—we presume excoriations—began to take place, and soon proved very destructive. The treatment consisted in general and local blood-letting, free inunction of the blue ointment into the back, cold douches to the spine, calomel internally at first, and then tart. of antimony in large doses.

Necropsy.—The sinuses of the brain much congested, as also the blood-vessels of the meninges generally; lateral ventricles containing a great deal of clear water. The cut surface of the cerebellum showed numerous bloody points; its natural surface covered with a layer of lymph, which extended downwards over the medulla oblongata. *Spinal canal.*—The cervical portion of the cord healthy; from the thoracic portion to the half of the cauda equina a

considerable quantity of fluid was observed, in which many flocculi floated, and which resembled albumen. The greater part of the lumbar spinal marrow was morbidly softened, and the dura mater corresponding to this softened portion was of a dusky red, and thicker than natural. The left brachial plexus was preternaturally red; the corresponding part on the other side could not be examined, through failure of the light.

SCHÖNLEIN AND DR. GÜTERBOCK.

"I took the simple way of coming to a conclusion in regard to this distinguished man (Dr. Schönlein, not Dr. Güterbock), and went to Berlin in July 1842." . . . "Güterbock's sketches are anything but Schönlein's living lectures; they are hastily-sketched outlines upon the spot, worked up at home from memory and the hospital tables. They are not taken in short-hand, but Herr Dr. G. generally perched high in the air upon the back of a chair, sets down short notes, without paying much attention to the patient, choosing from among the symptoms enumerated by Schönlein those that strike him as most important, and those observations of the physician which he esteems as particularly original and piquant. . . They are nowise to be taken as official documents, and means of judging of Schönlein and his clinical communications.—*Dr. H. E. Richter, in Schmidt's Jahrbücher*, Vol. vi. 1844, p. 379.

PHYSICIANS PRACTISING GENERALLY.

To the Editor of the Medical Gazette.

SIR,

I AM anxious to be informed, through the medium of the "MEDICAL GAZETTE," whether those gentlemen possessing the degree of M.D. from the London University, but who practise all the branches of the profession, take parishes, and send out medicines, are to be considered as physicians? And further, whether it is usual, and professionally right, for general practitioners to meet them in cases of consultation purely as such?

Your early observations upon these particulars, will much oblige, sir,

Yours most obediently,
A GENERAL PRACTITIONER, AND
AN OLD SUBSCRIBER.

Wycombe, May 27th, 1844.

[We are of opinion that there can be but one answer to our correspondent's queries. He who practises all the branches of the profession, who takes parishes, and sends out physic, is, to all intents and purposes, a general practitioner; and has no claim to

take the precedence which has by common consent been accorded to the physician, whatever the title or appellative he may have prefixed to his name. The general practitioner should meet such a man as a general practitioner, not as a physician.

We apprehend, on the other hand, that there is nothing to prevent the possessor of the degree of M.D. from the University of London, from practising generally, provided he be only qualified to do so by having a license from Apothecaries' Company, &c.—*ED. GAZ.*]

THE MEDICAL MUTUAL LIFE ASSURANCE SOCIETY.

To the Editor of the Medical Gazette.

SIR,

A FRIEND has just put into my hands a prospectus of "*The Medical Mutual Life Assurance Society*," in which it is stated that I am a member of the Provisional Committee; and that applications for prospectuses and shares may be made to the "*Provisional Committee, 28, Essex Street, Strand.*"

I beg to state that I am totally unacquainted with both the Society and its promoters, and that my name has been most unwarrantably used. Until this morning I was unaware that such a Society existed.

My neighbour, Mr. A. M. Randall, whose name is also placed among the Provisional Committee, has requested me, on his behalf, to disclaim all knowledge of, and connection with, the Society.—I am, sir,

Your obedient servant,
JONATHAN PEREIRA.

TO CORRESPONDENTS.

M. R., of Sunderland, should try another of the respectable medical practitioners of his town. We do not give professional advice to individuals in our editorial capacity, and through the pages of our journal.

Dr. S. surely cannot expect us to insert a criticism of a criticism, nearly as long as the article that has put his pen in motion. We recommend him to get the book, and read and study it for himself; it will well repay his pains.

We are asked by a correspondent what the subject of the next Harveian Prize Essay is. Can any one answer the query?

ON CANCER, AND DISEASES RESEMBLING CANCER:

*The Substance of a Clinical Lecture given at
St. George's Hospital, May 28th, 1844.*

BY CESAR HAWKINS, Esq.
Surgeon to St. George's Hospital.

1. *On Cancer of the Face.*
 2. *On Cancer of the Breast.*
 3. *On Cancer of the Tongue.*
 4. *Diseases resembling Cancer of the tongue:*
 - a. *Irritable Ulcers of the Tongue;*
 - b. *Syphilitic Ulcers of the Tongue;*
 - c. *Pooriasis, or Fissured Ulcers of the Tongue;*
 - d. *Carbuncular Abscesses in the Tongue;*
 - e. *Globular Tumor, or Scrophulous Abscess of the Tongue;*
 - f. *Common Abscess of the Tongue.*
- On the Operations for Cancer of the Tongue.*

As you have lately had several cases of malignant disease of different parts of the body under your observation, I propose to make some of these cases the subject of consideration in to-day's lecture.

1. And first I will read to you the case of a woman, Susan Wainwright, æt. 50, who was admitted on the 14th of May, with cancerous ulceration of somewhat more than the size of a shilling on the left cheek, which began on a congenital mole about a year ago, on which something like a wart then appeared, and ulcerated about five months back; to this she says caustic was applied in the shape of a plaster, but the disease soon recommenced. It now presents the appearance of an elevated irregular ulcer, with a hard tuberculated margin, discharging slightly from its surface, the discharge being rather fetid; the dark colour of the original mole is still perceptible in its circumference, which is elevated about a quarter of an inch. The skin around the ulcer is very hard, and

rather red; the hardness extends to some depth, and there are some six or eight small tubercles at the lower part just below the ulcer; these have existed about one month, and came after the caustic was applied; they are scattered an inch downwards towards the chin, and a little more than this in width; they are elevated, and whitish, and the skin covering them is very thin. Latterly there has been darting pain about the part; there is no gland enlarged in the neck, or elsewhere; she has no cough or perspiration; and the general health is said to be good, except that she has got thinner lately, and looks anxious; the tongue is clean, and the pulse rather full.

Now you have here an example of a form of malignant disease of the skin of the face; and the first thing which will strike you is that it has originated in a congenital mole. Nor is it at all uncommon for a congenital disease to undergo a change of this kind; you will remember, not long since, an example of it in a foreigner, who had a medullary tumor of the arm, in the place of a congenital nævus. There can be little doubt, too, I think, that any morbid growth may make a person more likely to have a cancerous tumor developed than another will be who has no unnatural formation of any kind; the cancerous diathesis existing, the new structure determines its local appearance at an earlier period; and for the same reason it is, for a time, more likely to be only local, than when cancer shews itself in the natural tissues. Secondly, you will observe, in this history, that an unsuccessful attempt has been made to destroy the disease by caustic, and the consequence has been probably an aggravation of the malady; it quickly returned, of larger size and more rapid growth, and with several new tumors around it; and such is generally the result of meddling with malignant diseases, either by the knife or caustic, without complete eradication of the morbid growth.

In the next place, as to the nature of the

malignant structure: the skin of the face is chiefly liable to scirrhus deposit, and that in three different forms; one of them is a superficial cancerous ulcer, of a low degree of malignancy, of which you will find an account in a clinical lecture of mine which has been published in the 29th volume of the *MEDICAL GAZETTE*; a second form is a fungous kind of scirrhus, of which I wrote an account which you will find in the 21st volume of the *Medico-Chirurgical Transactions*; and the third is ordinary scirrhus of the skin. The present tumor is not, however, any one of these forms of disease, nor yet is it a medullary tumor of the common kind; but it is something intermediate, as it were, between scirrhus and medullary disease, which, as you know, are easily traceable into each other, each proceeding gradually from well-marked cases of either species. Moles, and other previous new formations, when they become malignant, are usually of this intermediate kind; and the secondary tubercles are also of a different kind; instead of the flat, hard, tubercle, of the colour of the cutis, and like it in density, such as you can see in this preparation, the tubercles are, as here, more elevated, softer, yellowish in colour, with a thin covering of nearly transparent cutis, and a small base.

Believing its nature, then, to be of this kind, the result of treatment was more uncertain than in either of the varieties of scirrhus, particularly as secondary tubercles had already formed, and it was evident that much of the cellular tissue, and a considerable extent of the skin and subjacent structure, were affected, and the growth was rapid. Still, however, I was unwilling to leave the patient to her fate without one effort to destroy the malignant structure, in the absence of any distinct sign of constitutional taint, or of absorption. Malignant diseases must, if possible, be entirely eradicated either by the knife or by caustic, and each method has certain advantages and disadvantages: excision is perhaps more likely to be followed by foul secretion and secondary abscess, and the caustic is more apt to occasion erysipelas. As, however, so large an extent of the skin was diseased, I thought its destruction by caustic, though more painful than the use of the knife, would, on the whole, be the best mode in this patient, and the chloride of zinc is the kind of caustic which I generally employ, as a very effectual one, without danger of absorption, as with arsenic, and one which, applied to even part of a cancerous disease, will generally leave the rest, for a time, in a more healthy condition. Chloride of zinc was, when first proposed, mixed with flour; but as it is a deliquescent salt, I prefer adding sulphate of lime, which has been recommended by Mr. Ure; and you may

mix them in equal parts, or with a third of the chloride, according to the strength you wish it to be, *i. e.* according to the thickness of the parts you mean to destroy. Mixing this powder with an ivory spatula, that you may not decompose it, with a few drops of water, into a thick paste, you spread it on a piece of lint, proportioning the thickness of the paste to the depth of the part to be acted on; you may thus, if the paste is pretty hard, and there is not much bleeding or discharge, have very little running from deliquescence. The nurse was directed to watch its action, and apply a little carbonate of soda if any liquid oozed out. There is much pain from this caustic for some time, so that I ordered a dose of laudanum. In a day or two a poultice assists the separation of the slough; the swelling is generally considerable around it, and sometimes there is a good deal of fever. Where the thickness of skin is considerable, it may first be partly destroyed, as I did here, by *kali purum*, to lessen the most painful part of the action of the caustic; and you must look carefully to the surface, when the slough separates, to see that no morbid growth remains, and apply a fresh layer of the same caustic, or apply some other caustic—the strong nitric acid; or a caustic which the French are fond of—a solution of about half a drachm of nitrate of mercury in three drachms of nitric acid—till you are sure no part remains.

The result of the application I look upon as very doubtful, since the cellular tissue is much diseased; we must expect a great hole to be formed in the cheek, leaving much deformity; and perhaps the mouth will be drawn to the other side, as it is to an extraordinary degree in a gentleman I am attending, with Mr. Keate, for similar ulceration, by destruction of some of the branches of the portio dura; very probably also there will be a salivary fistula, from the duct being opened. The latter circumstance may, however, be remedied, in all probability, as it was in the patient from whom this cancerous tumor was excised with nearly an inch of the parotid duct, and with complete success for some years at least: a new duct may be established by perforation of the cheek, if necessary, and the use of a seton to keep it open for a time, and of course it matters little in what part of the mouth the saliva enters. I may observe, in conclusion, that for the few days we watched the disease, before I had made up my mind on the most eligible mode of proceeding, I used a lotion of prussic acid, which is very useful in malignant ulcers, and our notes accordingly remark that she experienced relief from its employment. [The slough has since separated, and the surface is healing, and looks sound.]

2. The next case I will bring before you

is one of cancer of the breast. The patient is Sarah Watson, *set.* 44, who was admitted on the 15th of this month, with scirrhus tumor above the right breast, the gland itself not seeming to be affected, or at any rate not much, as it is not hardened. She says it came from a blow on the breast, between two or three years ago, and the tumor was perceived about six months afterwards; about sixteen months ago it became attached to the skin, and shortly afterwards it ulcerated. The nipple is not tucked in, nor the skin affected over it; but the tumor itself is very hard, and the skin much puckered towards the central ulcer, and it is attached to the muscle beneath: it gives her a great deal of shooting pain at times, and two or three glands in the axilla are hardened and enlarged. The patient looks old, and feeble, and out of health, with short breath, and cough in the morning, and there is dulness of both lungs. She was confined fourteen months ago, and suckled her child till a week ago.

Here, then, is an example of malignant disease of the breast of the scirrhus form, and you perceive that the patient attributes its occurrence to an accident, a blow, six months before the tumor was perceived, and such is often the case; partly, perhaps, because every one likes to find a cause for their maladies, but in many cases, no doubt, because a blow or other accident really produces cancer in the injured part: it occasions its earlier appearance than might otherwise be the case in persons predisposed to the disease, acting in this respect just like the mole in the former case. In the next place we find that this woman had been confined since the tumor ulcerated, and has suckled her child with the other breast till a week before her admission. Now it is a common opinion that cancer of the breast is more common in unmarried females, and in those who have not had children, than in women who have borne them; but I must confess that I do not think there is any ground for this doctrine, for I have repeatedly seen cancer of the breast, or of the uterus, in persons who were at that very time suckling or becoming pregnant, and in a great number of married people; there are so many more married than unmarried females, that cancer ought to be more often seen in the former, but I suspect it is not only so, but frequent enough in married women to make the proportion of cases equal in both states.

The case before us appears to me to be not at all adapted for operation, and that for several reasons: first, the tumor is separate from the breast, situated, that is, on its outer part, and only becoming adherent to it as the disease advances; it is hard and dense, and contracted, and such a tumor is always more slow in its progress than when cancerous matter is infiltrated in its tissue so as to

affect the whole breast. You may contrast the appearance in these two preparations. If, then, the object be to remove the whole disease, such a tumor is on the whole favourable for operation; but if, on the other hand, circumstances render the entire eradication of the diseased structure impossible, the slow growth of this form of disease makes the operation inexpedient: this is the case here, and therefore we are not called on to meddle with the tumor itself, which may be sometimes advisable, even when a perfect cure cannot be looked for, in order to make the sufferings of the patient less. Secondly, ulceration has here taken place; the skin is drawn in, and altered in texture, and although the nipple is at some distance, and not at all retracted, yet probably the cellular tissue and skin are so much affected, that a return of the disease in the part itself would not be unlikely if the tumor was removed, and a painful operation would have been undergone for nothing. The disease, however, has gone further than this; one or two of the glands in the axilla are enlarged, and so hard that their enlargement is not from irritation only, but must arise from some poisonous matter in their structure. The glands in the axilla are very often enlarged in cases of cancer, without ulcerating, so that if the tumor of the breast is in a very bad state, it may with much advantage be removed in some cases, although the diseased glands are left: we have seen, however, that the local state does not here indicate an operation, and therefore the contamination of the glands is an additional reason against it. But then, in the next place, our patient is thin, and of a naturally spare habit: now this also is a circumstance to be considered in reference to the question of operation, in many cases of cancer of the breast: there can be no doubt, I think, that the progress of the tumor is much slower, and it is less likely to bleed from fungous granulations, in a thin person, than in a fat and bloated one; it is very probable that the kind of tumor seen in a given case is much influenced by the natural temperament, and hence, perhaps, it is that the small contracted stone-like tumor is generally seen in those who are of spare habit, like our present patient, while the large voluminous tumor is as commonly found in stout persons, whose circulation is, nevertheless, feeble and weak, so that an operation is more dangerous in them than in thin persons, independent of the larger wound required, although the more rapid growth of the large mass would make its removal more desirable, if it were not for this reason. But in the next place our patient has a cough, and dulness of the lungs, and cannot easily lie on her left side, and therefore although it may be only bronchitis that she is suffering from, yet there may be some commencement of that state of chest from

which so many die who have a cancerous tumor of the breast: there is no reason to think, indeed, that there is water within the pleura, which is often the case, nor is there apparently more disease on the same side as the tumor, yet there may be some beginning of tuberculation of the pleura, or of cancerous deposits in the lungs, which are very difficult to discover in an early stage, unless it be by slight dulness on percussion, as there is a free entrance for the air between the tubercles, and little increase of vascularity for some time after they have begun to form. Finally, our notes say that she looks old and feeble, and her complexion is very unhealthy. A good deal is said of the peculiar look of a person in whom the whole system is under the influence of cancerous disease; a sallow or leaden colour, and sunk expression, are expected, as evidence of the disease being no longer local: I cannot say, however, that this is at all universally true; sometimes, no doubt, you cannot hesitate in saying that a patient with a certain appearance of countenance does in all probability labour under a cancerous cachexia, but the appearance is easily simulated by other diseases; I think, for example, you would hardly distinguish, in many cases, from her looks alone, whether a woman was dying of cancerous disease of the uterus, or was simply exhausted and drained of blood by a polypus of this organ. It is therefore not at all improbable that this woman's emaciated and weak condition may arise, not from absorption of cancerous matter into the blood, but from fourteen months suckling, with, perhaps, very scanty food.

As, then, from the various reasons I have alluded to, it would have been wrong to operate in this case, I have yet kept her in the hospital to see how much of her appearance, and of her suffering too, depends on the cause I have last mentioned, and you will observe whether she improves under good diet and the use of sarsaparilla, which I have put her upon the use of. Even if there be real cancerous cachexia, the same plan of treatment will still be the proper one, and it will much retard the progress of the disease in the system, and check the growth of the morbid deposits. There cannot be a greater mistake than to reduce a person labouring under cancer by low diet and leeches, which are often employed in order to relieve pain by checking inflammation.

A case was under my care many years ago which very clearly proved this point: a young woman, who was suckling, like our present patient, came to me with a cancerous tumor of the breast at the early age of 29, which was unfit for operation, and after a little while she was induced, as being more convenient from the situation of her home, to attend as an out-patient of another

hospital, where she was lowered and had leeches repeatedly applied: she came again to me after a few weeks, suffering dreadfully from increased pain, and looking as if she was rapidly sinking, and so she would have done, if this plan had been continued: I put her, however, on a better regimen, and gave her sarsaparilla, as we are doing for this case before us, and the result was that she soon got stout and well comparatively, and hardly experienced any pain in the tumor, and her life was obviously prolonged for more than a year by the difference of treatment. Support your patients, then, but yet avoid stimulating them too much, for this is equally injurious.

[The woman has very much improved since the 28th of May, when this lecture was given, and has a comparatively cheerful aspect, with much less pain, and has gained flesh considerably, and nearly lost her cough.]

3. A third example of cancerous disease was shown you in the case of Richard Crandley, æt. 45, who was admitted April 17th, with malignant-looking ulcer in the tongue. He says it came about two months ago from the irritation of a rough back tooth, and that its first appearance was like a small cut in the tongue; it has not given him much pain till lately. There is an irregular excavated ulcer, with a hard base, extending from the back part of the left side of the tongue to the frenum and middle part: its circumference is as large as a walnut: there is also some superficial ulceration of the soft palate just where this ulcer of the tongue comes in contact with the palate. The hardness very nearly reaches the gums of the last molar teeth. No gland is enlarged. He suffers some pain from it, especially at night. He never had the venereal disease. The patient is of a dark, sallow complexion; and his tongue is foul, and covered with a dirty yellow crust. Pulse natural.

This is an example of cancer in the tongue, which is generally of the scirrhus kind in this organ; and in the history we may notice that it appears to have been excited by the irritation of a tooth, which has the same effect as the blow in the former case of determining the locality of a cancerous tumor in those who have already a cancerous diathesis. But there are several other diseases of the tongue which bear much resemblance to cancer in different stages of its progress, and, from the questions which have been put to me on the subject of this case, I am induced, before speaking of what has been done for it, to point out to you, in a rapid sketch, the various disorders of this organ which may be confounded with cancer.

a. First, then, there are *irritable ulcers* of the tongue and lips, which are excited by the irritation of rough teeth, as this disease

was; and they are often very painful, and interfere much with the speech of the patient, and with his eating and swallowing; they are attended with much salivation, and have a foul and phagedenic surface, and the patient is frequently thin and sallow, and haggard, as if he was suffering from cancerous cachexia: but there are generally several of them, while cancer is single; and there are many signs of indigestion on which the irritability depends: the tongue was loaded indeed in this case, but it was with a thick dirty yellow crust, which soon cleaned, and arose from irritation chiefly; and the surface elsewhere was not chapped or reddened, as it is with the irritable ulcer. There is usually an habitual state of constipation, or an occasional attack of diarrhoea, or the appetite is bad; and the irritable sores, though the edges may be hard and elevated, have no uniform hard base, or tumor, below them in the substance of the tongue, which may be commonly felt in cancer, and was, in our patient, as large nearly as a walnut in its circle. This drawing was taken by Mr. Hewett from a patient recently under my care, and shows you very well the appearance of those irritable ulcers of the tongue; they were excessively painful, and when in this state are best treated by repeated small doses of laudanum, with some carbonate of ammonia in the course of the day, following generally an active dose of calomel, with Dover's powder and a saline purgative; and warm water, or some stale bread partly masticated, and allowed to lie as a poultice on the ulcers, will be the best local treatment. After this, (or at once, if opium is not necessary), the condition of the general system may be improved by alterative doses of blue-pill, or mercury and chalk, with bitter infusions and carbonate of potash; or if the patient is thin and sallow, by sarsaparilla, with small doses of bichloride of mercury. Locally, you may apply the linimentum seruginis, if the ulcers are foul, taking care the patient spits it out again; or a gargle of decoction of bark and myrrh when white sloughs cover them; and they will readily heal, and much pain be removed, by the use of solutions of caustic, or lunar caustic in substance, avoiding such a quantity of it as to avoid blackening the teeth; and wherever rough points of the teeth keep up irritation, they must be filed down, or the teeth extracted.

b. Secondly, a syphilitic sore on the tongue bears much resemblance to cancerous disease. There is here a very good drawing of a secondary syphilitic ulcer from a patient who was under my care in the hospital some years ago, and you may perceive that it may form a large excavated ulcer, half an inch deep, with elevated and somewhat hard margins, and a dark livid colour of the sur-

face around it, the bottom of the ulcers being covered by dark brown or nearly black sloughs. The edges, however, are less fungous or warty than in cancer, and, though hard, there is an absence of the firm structure below and around the ulcer which is formed by the new growths of carcinoma; the foul excavation extends into the cellular tissue, but you can feel that the substance of the tongue is sound; and then there is commonly something in the history of the patient, or there is some other symptom present, a spot of psoriasis elsewhere on the tongue, or on the tonsils, or palate, or some eruption on the skin, which excites attention and points out the nature of the disease; and when ascertained it quickly gets well, as this did, under mercury; or under sarsaparilla and iodide of potassium, if the mercurial treatment is contraindicated. Our patient, we perceive, denies having had the venereal disease, and has nothing like a syphilitic appearance in the present state of the tongue; he had, indeed, slight ulceration of the palate, but it was obviously from the contact of the tumor, and soon healed.

c. There is, in the next place, the fissured or dyspeptic ulcer of the tongue, originating in psoriasis very often, so that besides the ulcer a flat plane surface is often seen in another place, from which the papillæ have been absorbed, or there are chaps on the tongue which show the irritable condition of the mucous surface of the alimentary canal; but the dyspeptic ulcer much resembles cancer if there is a deep fissure with elevated fungous margins cutting the tongue in portions, interfering with the patient's speech, and causing a good deal of salivation, and still more, if there is, as in this drawing, a condensation of the cutis over a large prominence, with irregular, firm, warty excrescences. Here, too, however, there is an absence of the morbid structure below the projections; the fissure is frequently in the median line, while in cancer the disease is generally on one side only of the raphe; the rest of the tongue is chapped and irregular, while in cancer two separate parts are very seldom diseased; and there are many of the signs of irregularity of the digestive organs: although perhaps the patient will say he is in good health, yet, if cross-questioned, he will acknowledge that there is more constipation than there used to be, from deficiency of bile, or there is occasional diarrhoea, or the urine is high-coloured, with deposit of lithates; the tongue is furred, and the sleep is disturbed, or the appetite lessened; often the countenance is greasy, with copious sebaceous secretion, and the pulse is generally quick, and small, and irritable. Sometimes you will cure these ulcers, and get the prominences in great measure absorbed, by the same general remedies which I have just

spoken of for the common irritable ulcers. Sometimes alkaline purgatives, with a few drops of colchicum-wine, every morning, will do good for a time, till other remedies of a tonic kind can be given, of which in general the best of all is arsenic, from three to ten drops of the solution being given three times a day, with an occasional rhubarb and magnesia purgative to prevent its injurious effects.

d. Another form of disease which in some measure resembles cancerous ulceration is a kind of *carbuncular suppuration* in the tongue. Sometimes a number of small tumors are seen, of the natural colour, and of the size of peas, which slowly suppurate, and little orifices lead into cavities below the cutis, lined by white sloughs, each coming separately forwards, and the whole lasting a considerable time; sometimes a smaller number of larger and darker coloured elevations take place, and unhealthy brownish-white sloughs are exposed, the cutis being undermined by them; still, however, the disease being only in the cellular tissue, without hardness, and not extending into the substance of the tongue. But in other cases deeper and larger sloughs will occasionally form in one or two places, the cavity being filled by foul dark-brown, or black sloughs, and the skin sloughs to some width, deep fissures being left when the sloughs come out. In all cases, the absence of hardness, and in most the number of diseased parts, readily distinguishes them from cancerous ulcers, although a superficial glance might lead to mistake. Such carbuncular inflammation as this is seen chiefly in persons of bad system, weakened by intemperance or starvation, or they occur as the sequelæ of syphilis, or the patients are otherwise brought into a state of cachexia. They require generous diet, and the use of the balsams locally, and sometimes the undermined skin, to some extent, must be laid open to expose the cavities and let out the sloughs.

e. There is occasionally seen a *globular tumor* in the substance of the tongue, which has been supposed by Mr. Travers, who has described it, to be an encysted tumor, but which, I should rather suspect, is a scrofulous abscess; for although such a round smooth body as he speaks of sometimes disperses, and might be considered dyspeptic, I have also seen them suppurate slowly as a chronic abscess would do, and discharge a thick cheesy pus; and an encysted tumor does not differ from what is observed in other parts. If there are both forms of disease, you may recognise them by their roundness and smoothness, as contrasted with the harder and more irregular shape—quadrangular, or whatever it may be—of cancer of the tongue. You will see them disappear some-

times under the use of mercurial alteratives and bitters, or iodide of potassium, taking a year or more to disperse altogether; or you may be obliged to open them, as scrofulous abscesses. I have very seldom seen anything, however, except common encysted tumors, or scrofulous deposits ending in suppuration.

f. You will in the last place occasionally meet with a *common abscess* of the tongue, a swelling quickly ending in suppuration, in comparison with the last scrofulous abscess, and soon filling up and healing. Neither this, however, nor the last, except that there is a swelling, can easily be mistaken for the hard tumor of cancer, nor for its ulcer after suppuration.

Having, then, taken this survey of diseases of the tongue which may be confounded with cancer, let us now return to our own case, which is evidently no one of these; but an example of carcinoma of the scirrhus form. Now the removal of cancer of the tongue by operation is very rarely indeed successful, and the reason is obvious if you examine these preparations on the table; it is this—that there are almost invariably separate tubercles in the neighbourhood of the original tumor; they are commonly in the substance of the organ, varying in size from a pin's head to half a pea's; but I have seen them, in a patient of Mr. Keate, developed superficially in the cutis around the cancerous ulcer. I cannot say that I have myself seen a single example in which the operation was not followed shortly by a return. The tumor in this case was even less likely than many others to be entirely removed, as it was of very rapid growth, having only been discovered two months; and the palate was ulcerated, and possibly contaminated, and the patient had a sallow unhealthy countenance; still, however, it did not seem right, as no gland was enlarged, to abandon him without any attempt to save him from a very miserable end. I did not do it immediately after his admission, however, in order to be certain that the ulcer of the palate was not of the same character, and to see how quickly the ulcer was spreading; and I used a solution of the chlorinated soda, of the strength of one pint of the saturated solution to twenty of water, and gave him for a few days some arsenic; not that I doubted its nature, indeed, but that you might see its failure, and it could do no harm, and something must be given or done till we had determined on the operation. You saw, then, that on the 26th of April the ulcer on the palate was nearly well, and on the 29th, the notes say that great part of the ulcer of the tongue was healed, but that the hardness remained; and on May 2d, an operation was performed.

There are two methods by which cancer

of the tongue may be removed; namely, excision by a bistoury, or by ligature. Where the disease is situated at the front or sides of an organ, I think you may take your choice; and the knife is perhaps the best way of doing it, as it is easily effected with little future mischief; while the ligature sometimes causes a good deal of swelling of the tongue, and difficulty in breathing and swallowing. I have known a patient half suffocated, indeed, from the large swelling; pushing the tongue backwards, and filling the mouth, and ulcerating it by pressure against the teeth; and you can in this part easily tie the bleeding vessels. But in our patient the disease was far back towards the root of the tongue, and I think excision is here quite out of the question, from the great size of the lingual and ranine arteries endangered by the knife; and you saw that even with the ligature the hæmorrhage was attended with some danger; the tongue being very brittle, and easily breaking down under the silk. The lingual artery has sometimes been tied separately for hæmorrhage, or attempted to be tied without being found. I determined, therefore, on trying to remove the whole disease by ligature. The mode in which I did this I have already explained at the time of the operation; but as some of you may not have been present, I will just say to you, that in the usual way of tying a large tumor, by a double ligature, some part is liable to escape, as in this diagram; if you tie the

without any slipping (in the line c and d). One thread unfortunately broke, so that I was obliged to modify this plan, and pass the eyed needle again through the back part of the tongue, to secure the whole if it were possible.

Our notes remark that he lost about six or eight ounces of blood at the operation, and secondary hæmorrhage occurred to the extent of about 14 ounces; this was, however, controlled by astringent injection of alum, and iced water, and by pressure by the finger; but it broke out again in half an hour, when a ligature was passed through at the base of the tongue, and tied, which permanently stopped it.

Our patient had very little of the swelling I have just spoken of, having on the next day, our notes tell us, some difficulty of swallowing, but none of breathing; and on the 8th, the ligature was loose, and no hardness was perceptible. Some care is required during the separation of the slough, that the tumor does not again become organised; for the ligature can scarcely be tied so tight but that some little vessels in the centre may escape pressure, and thus allow blood again to enter when the circumference has become loosened by ulceration, and the ligature no longer preceses on the remainder; the consequence is (and I have seen the same in tying large nevi), that a supply of blood again enters, and parts apparently quite dead and black are again endowed with vitality, and would soon adhere to the surfaces from which they have been cut off by ulceration; and the disease would be soon as large as ever, unless on the third or fourth day, when the ligature begins to be loose, you applied a fresh one, so as to finally destroy the remaining attachment. This, however, was not necessary in this case, and on the 15th of May, the cicatrix had contracted, so that the man was desirous

ligatures very tightly, they may slip in this line (a), and so leave little portions beyond them; or else, to secure the whole, a good deal of healthy substance must be included, as in the line (b). The ligature I used was therefore made to perforate the tongue twice; the first time quite towards the front of the tongue; and the second time quite behind the back part of the tumor; by then cutting both the loops on the surface of the tongue, the under or middle loop can be tied tightly in a longitudinal direction (as from a to b), cutting off the whole length of the tumor from the body of the tongue, and then the two ends can be tied quite transversely, so as to secure the whole tumor

of being an out-patient, promising to shew himself from time to time.

On the 20th, the notes remark, the ulcer is nearly cicatrised; the voice is much improved, and he has no pain; but they add, the back part of the tongue attached to the palate and jaws has a reddish prominence of suspicious appearance; and on the 27th, a week afterwards, the return of the disease was already evident. The ulcer remained nearly healed, but with much hardness below and around the contracted cicatrix; the surface of the anterior arch of the palate, and the membrane passing to the under part of the jaw, has some distinct warty growths rising from them.

But the operation having not been successful, why not operate again? I must confess that the chance of doing good appears much too small to justify further interference. The disease has returned, and is increasing so rapidly, and its progress towards the palate and jaw is already so considerable, that it would be sure to fail; and I should run much risk of hastening the progress of the disease; besides the chance of hæmorrhage, which has just been so great, the unsuccessful operation would add to the irritation and rapidity of the next growth; nor does the application of any caustic seem, for the same reasons, admissible. It is, however, a miserable fate to which we leave the poor man, with pain, and irritation, and difficulty of swallowing and breathing, from its progress backwards. You can here see, for example, the epiglottis pushed back, and the arches of the palate much affected, as they threaten to become in our patient; then the patient is half-starved, if he escapes suffocation, unable to swallow even the softest food from pain, and inability to move the parts in the throat, and sickened as he often is by the discharge, which is as foetid and horrible as a mixture of the fætor from a bad mercurial salivation and diseased bone at once, may be supposed to be. Neither do I think there would be any advantage gained by another method of applying a ligature, which has been sometimes done by incision under the chin, between the muscles of the tongue; it is difficult, indeed, as you saw, to apply the ligatures by a needle in a handle, when the disease is far back in the mouth; and for some cases of considerable size, some such method as is described by Mr. Arnott in the *Medico-Chirurgical Transactions*, may be practised. I will not detain you to explain the plan, but you can understand the course of the ligatures by looking at this drawing, which accompanies his case. In our patient, however, the difficulty is not so much from this cause, as it is from the implication of the adjacent structures in the disease. [In a week or ten days after this lecture, the

posterior arch of the palate, as well as the anterior, shewed signs of new malignant growth, and the disease seemed likely to make quick progress.]

ON

FRACTURES OF THE VERTEBRÆ.

By W. LYON,

Lecturer on Surgery, and lately one of the Surgeons of the Glasgow Royal Infirmary.

(For the *Medical Gazette*.)

[Concluded from p. 364.]

THE varying consequences of different kinds of lesions of the cord are well shown in the three cases. Analogous to what is observed from similar lesion of the brain, the small, pointed, depressed spicula on the cord occasioned the most severe symptoms, and the most rapid death, the man dying on the 16th day after admission. In M'Gill, in whom there was an equal amount of pressure on the cord as in Gallagher, who died on the 16th day, but in whom the pressure was made over a larger surface, and by much more obtuse portions of bone, the primary local displacement must have subsided; nature had commenced osseous anchylosis of the intervertebral surfaces, and had nearly completed an osseous case, surrounding and supporting the spine at the fractured part, and in so far restoring the functions of the spine, that power and voluntary motion returned in the inferior extremities, when secondary inflammation seized the injured parts, and this, combined with the deprivation of the functions of the cord in the parts below the seat of fracture, and the effects of extensive ulceration, caused death; but not until nearly two months subsequent to the accident.

It has been observed in bruising, laceration, or pricking of nerves, that the local effects, and general disturbance, though there is not entire loss of function, are far greater than when the nerves are divided: in the latter case the function is instantly interrupted, and the local consequences are not materially different from those occurring in less vital tissues: in the former, viz. bruises, lacerations, or pricking, the functions may be destroyed, perverted, or exalted as in paralysis, spasm, neuralgia, tetanus, &c., and added to these there is

usually high local and much general excitement.

The case of M'Lusky, in whom the cord was entirely divided, goes to prove that in the nervous trunks, so in the spinal cord, complete division, so far as more immediate effects are concerned, is a less severe and a less quickly fatal lesion than much bruising, pricking, or tearing; for whereas one of the other two patients died in 16 days, and the second in two months, M'Lusky lived for 13 weeks, or two months and a half, and died less from the *local* effects of the injury, (for the divided extremities of the cord were rounded, cicatrized, and healthy,) than from interruption to the organic functions, which are in so far dependent on intact conditions both of organic and spinal nerves*.

The *displaced* and altered course (for I do not think they could have *contracted* so as to have accommodated themselves to the altered relations of parts) of the aorta, vena cava, thoracic duct, and sympathetic nerves, by the riding of the portions of the spine, would have led us to expect some disturbance of the functions of one or all of these important organs: no proof of the correctness of this expectation existed during life, and examination into their condition after death was not permitted.

Observation of cases of paraplegia proves that the organic functions of digestion, chymification, chylification, absorption, general and local nutrition, secretion of urine, &c., &c., can proceed independently of the influence of the spinal cord; but the tympanitic abdomen, constipated bowels, ammoniacal urine, proneness of the tissues to sloughing and ulceration, afford evidence that the cord ministers to other functions besides those of secretion and power of motion. On the other hand, the conditions in the cases detailed do not at first sight corroborate the views of Dr. Marshall Hall, as to the spinal cord being in a great measure apart from the cerebrum, the organ for the reception of external impressions, and transmission of consequent power of action independently of the will.

For, the entire division of the cord at

the third dorsal vertebra in M'Lusky, as it was far above the described seat* of the reflex centres, should have permitted the production of the excito-motory actions from tickling, pricking, &c. Now these modes of irritation were often practised in various situations; the large ulcers on nates, &c., were frequently coarsely rubbed, but no motion of the paralytic extremities could be excited, or was ever observed to occur from natural causes.

The phenomena remarked in the case of M'Gill are at first sight favourable to the views of Dr. Hall. But motion of the limbs did not occur from tickling or pricking of the soles until four weeks after reception of the fracture, and only after sense of heat had been experienced in limbs, and power of motion in toes of right foot had returned. The return of voluntary motion, and the feeling of heat in the recently paralysed parts, showed that the integrity of the cord was becoming restored; and it may be feebly insisted that the excito-motory actions manifested three days later, were only the slight, waning remains of the voluntary function. At all events, the seeming excito-motory actions occurred at the period at which there is every reason to believe improvement had furthest advanced in the injured part of spine.

Pain was again felt in the seat of injury, and in all likelihood inflammation, ulceration, and suppuration, supervened in the fractured vertebra, intervertebral cartilages, and surrounding tissues; and neither voluntary or involuntary motion nor sensation returned. On the views of Dr. Hall, the interruption of communication between the cerebrum and injured part of the cord should not have prevented the manifestation of excito-motory actions; and supposing his opinions correct the absence of those actions can only be accounted for on the supposition that the effects of the injuries to the cord had extended to the seat of the reflex centres, and had, as is usual from disease, destroyed the functions of the part. In this manner shock or concussion would paralyse the functions of the cord below the seat of injury at first†; afterwards inflammation

* In *Observations on Injuries of the Spine and Thigh-bone*, by Charles Bell, London, 1824, p. 25, there is the case of a child detailed, who lived 13 months after an accident which divided the cord, the child then dying of croup, but whether connected with the injury is not stated.

* Dr. M. Hall, *On Diseases of the Nervous System*, p. 227, par. 111.

† Dr. Hall on *Diseases of the Nervous System*, p. 226, par. 1109.

‡ *Ibid.* p. 217, par. 1208.

or its consequences would act in a similar manner; and by the time these passed off, the capability for action had become exhausted, from communication with the brain, on which it partially depends, being interrupted.

It is asserted by some that Dr. Hall's views do not satisfactorily explain the phenomena exhibited in experiments nor the symptoms existing in morbid conditions. Among other questions, they ask, how is it that the reflex actions are not present in every case of paraplegia the cause of which is above the disturbed locality of the reflex centre? This objection is answered by the statement contained in the preceding paragraph. But sceptics on this subject propound other queries, such as—if the spinal marrow in man, independent of the cerebrum, be the seat of the nervous agency for conferring muscular power, how does it happen that the amount of muscular power is so very insignificant, as is shown in pricking, tickling, &c., when connection with the cerebrum is cut off? It will be replied, that this is from the absence of the influence* of the will, which, however, on the supposition of Dr. Hall, should not give power, but only permission for its being called into action; and the opponents to his opinions contend that the manifestation of considerable power without the influence of the will, or from pricking or other modes of excitement, should occasionally appear, which, in experiments or injuries where the cord is entirely divided, has never been found to happen. They likewise propound other queries on the subject: they ask—what is the difference between the phenomena shown by pricking the muscular substance in a recently amputated limb, in which of course there are innumerable nervous filaments, and those which are sometimes evinced by tickling or pricking portions of the surface below the diseased or injured part of the cord in paraplegia?

In both cases the muscles above the part pricked or pinched contract simultaneously with the application of the irritant. In the one instance, however, viz. the amputated member, the capability to contract ceases in a short time: in the other it frequently continues for a long period. But does not this difference depend upon the one retaining circulation, and the influ-

ence of organic nervous connexions, and the other being deprived of all kind of vitality; and as the local reflex actions are shewn in the one when entirely disconnected with the brain, may they not also reside in the nerves of the other, of course extrinsic to the cord, and may not their continuance in one, and not in the other, arise from retention of the circulation, &c., as above stated?

To prove that the excito-motory actions depend on the cord, Dr. Hall cut across the sciatic nerve in one limb of an animal the spinal cord of which had been previously divided, and left the sciatic nerve of the other limb intact. In the limb the nerve of which was undivided he found the excito-motory phenomena to be present, while in the other, where the nerve was cut across, they could not be detected. But the conclusion inferred by Dr. Hall from this experiment is doubted. He acknowledges that the excito-motory actions are not always present immediately after reception of the injury which causes the paraplegia, the concussion or shock probably paralysing the excito-motory centre; in the same manner, it is insisted, that the injury caused by the division of the sciatic nerve paralysed its functions for the time being, and that therefore the experiment does not invalidate the opinion of the source of the reflex actions residing in the nervous trunks, as well as the spinal marrow.

By stating here these arguments against the doctrines of Dr. Hall, I do not wish to be understood as assuming for them any great force, far less absolute correctness; but I think further consideration requisite before implicitly subscribing to the views which hold that there are several reflex arcs—that they are all situated in the spinal cord, and are independent alike of the cerebrum, on the one hand, or the nerves which emanate from the cord, on the other.

I have already briefly dwelt on the difficulty, as evidenced by the preceding cases, in most, and impossibility in many instances, of severe injury to the spine, of deciding positively whether or not fracture be present. If there be any difference of opinion as to the general utility of examination with the view to detect fracture, there will be more as to the hurtfulness and even danger of subjecting with this object the pa-

* Ibid. p. 216, pars. 1036-7

tient to much motion; as thereby the fractured portions and displaced vertebræ, acted on by the weight of the body, muscular action, and it may be, force exerted by the surgeon, may be made still further to press upon and injure the cord.

On the presumption that due care and skill were exerted in the examination of the three cases described, and that the reasons adduced as to the difficulty of exact diagnosis are allowed validity, the futility of much manipulation in spinal injuries will be admitted. But while observations of the spinal contour, and careful and gentle pressure and counter-pressure, are not to be omitted, the aid afforded by the stethoscope should not be neglected. When we recollect the delicate organization and important functions of the cord, the loose and sharp osseous fragments seen in the preparations, and the stretched and lacerated ligaments permitting motion and displacement of the fragments and vertebræ from each other, we need not dwell on the impropriety of forcible digital pressure over the injured parts, or rude or frequent change of posture of the patient, in order to attain our object.

Where fracture does not exist, it would certainly be advantageous to be able to determine its absence, for we would then be authorised to practice more actively than if it were present; otherwise, I am not sure that its detection would be more than negatively serviceable, by guarding us against the dangers of pressure and motion. But this opinion has not been held by all practitioners, for when not only fracture but displacement has been found present, there are examples where attempts have been made to replace the parts by extension. These may be beneficial, dangerous, or unserviceable, and we believe it is impossible to predicate which of them may result in any given case, and therefore the risk of their employment in any. In the instance of M'Lusk, where the cord was divided, and the vertebræ overlapped, extension might have remedied the displacement; but we do not possess means to retain apposition in the spine as in fractures of the long bones; and therefore the least motion of the patient, aided by contraction of the muscles situated upon the spine and trunk, would have caused the

obliquely broken vertebræ again to have slid downwards and forwards.

Whether, if displacement could have been prevented, union of the divided cord would have ensued, we can only conjecture as probable from the analogy witnessed by reunion of divided nerves. The intervertebral ligaments and intervertebral cartilages were in this case torn, and had the extension been carried farther than just to have brought the overlapping portions and spine to a straight line, the strain would then have been thrown not only upon the muscles, but also upon the aorta, vena cava, thoracic duct, and nerves running upon the spine, and instant death might have been caused, shewing, if not the most imminent danger, the nicety requisite in such procedure. Similar conclusions are deducible from the state of the parts in Gallacher. The spine might have been made straight, and the displacement have been removed, but the intervertebral substance and articular and general ligaments being lacerated, the extension might have told upon the cord or important organs in front of the spine, and increase of injury, or instant death, have followed; while it would have been quite impracticable to have maintained adjustment. In addition to these objections, extension, in the third case, that of M'Gill, by making the cord straight and tense at the point where it was pressed upon by the sharp fragment, would have caused the fragment to have been more deeply depressed into the cord.

The objections against attempts at replacement by pressure directed transversely to the line of the spine, pushing the one portion backwards and the other forwards, are not so weighty as against the practice of extension; but the fragment would not be easily, if at all, replaced where there is overlapping, or if the oblique processes were unbroken; and if the pressure were carried in the least too far, the same evils would result as from extension.

Those points considered, I conclude, that by the weight of the body placed upon a hardish plane surface, as a mattress, we will, if not so effectively as concerns replacement, accomplish at least safely all the advantages within our power; and that although patients have escaped where the practice of extension has been followed,

that nevertheless it is imminently dangerous, and may be instantly fatal.

Not more generally admissible or efficacious, though not so immediately dangerous as extension, is the proposal, which has likewise been practised, of trephining, or otherwise removing, a portion of the osseous canal in order to remove depressed bone. There are few cases, indeed, in which appearances will be so distinct as to enable us to determine on its propriety; and it is a practice not merely of a negative kind, for if not beneficial it will be deeply injurious, by converting a simple into a compound fracture, which, if dangerous in other localities, is incomparably more so where the spinal cord is concerned.

Nor, besides its remote consequences being hazardous, will its mere performance be an easy or safe matter. The soft parts being turned aside, we have, in a deep and narrow wound, to work with the trephine, or Hey's saw, obstructed by the remains of muscle, obscured by blood, in just fear of wounding the cord, and the difficulties greatly increased, if, as in M'Lusk's and Gallacher's cases, the saw has to work upon numerous loose portions of fractured oblique and transverse processes heaped on each side of the spinous processes. I can conceive a case in which it might be justifiable to attempt this operation; as, where a spinous process was unequivocally depressed, and the spine otherwise apparently intact, and where symptoms of dangerous pressure existed. Such a case is not likely to be met with, and seeing how vague is the diagnosis in spinal injuries, and how uncertain the locality and extent of the lesion, the circumstances must be very rare where the operator who attempts this procedure will not deserve the accusation of hardihood or rashness rather than the credit of prudence. Yet M'Gill's case was one in so far well calculated for the practice we have been reprobating. The main and most dangerous lesion was the small sharp fragment depressed into the cord. The ligaments, too, were lacerated, the intervertebral substance injured, but these might have been recovered from had the fragment been removed. There were not, however, any signs of fracture; the exact locality of the injury could not be elicited; though fracture had been evident, its kind or situation

could not have been ascertained, and the operation was therefore inapplicable.

In fracture of the vertebræ, with partial dislocation, as in Gallacher, the operation of removing a portion of the osseous canal, in expectation of lessening the pressure, would have been not only totally inefficacious, but decidedly hurtful. In such an instance the pressure is not confined to the posterior part of the cord, the anterior surface being likewise stretched over and compressed upon the anterior part of the vertebræ*; the removal of the posterior portion would here, too, be of course unserviceable, the pressure anteriorly remaining undiminished.

The bad effects of motion will, we suppose, be assented to. Where there is appearance of displacement, few, we think, will have the temerity to employ extension or the trephine. Supposing there be not any impediments to replacement excepting muscular action, there still remains for consideration the agency to be obtained for restoring the line of the spinal column by the weight of the body placed on a plane hard surface.

We have described how, in opposition to every means for lessening the bad effects of pressure on the paralysed parts, that numerous large ulcers, which would have proved dangerous apart from the other lesions, rapidly formed on the patients who were under my care. We are therefore placed on the horns of a dilemma. The weight of the body resting on a hard plane surface is the gentlest means of obtaining and keeping up the proper position in fractures of the spine with displacement; perfect repose is likewise most important: but the more the patient rests in one posture, and the firmer the substance he rests upon, the more rapidly do the ulcers show themselves and extend. Fulfilment of all rational indications, then, the only measures likely to be useful for restoring the healthy line of the spine, and to permit exertion of the sanative powers of nature, are, in another view, viz., from their tendency to induce sloughing or ulceration, incompatible with the safety of the patient. The means, therefore, the most beneficial in one respect are unfortunately the most hurtful in another.

* See Plate 2nd.

As far as possible to obviate the effects of pressure, I employed frictions, air-pillows, change of posture, the hydrostatic bed, and stimulants to the sloughing and ulcerated parts, but without advantage; sores, some of them the size of a tea-saucer, forming over the sacrum, trochanters, &c., and exposing the bones.

It may be said that what I gained by change of position I lost by its tendency to increase the causes of the paralysis and loss of sensation; the best proofs that this was not the case were the existence of the sloughing before change of position was had recourse to, and its not extending more rapidly after its employment. Floating in the hydrostatic bed is less favourable for removing displacement of the broken vertebræ than is reclinon on such a surface as that of a hair mattress; but by equalizing the pressure from the weight of the body, diffusing it over nearly the whole surface, I anticipated that ulceration of the soft parts would have been prevented. Rational and ingenious as is Dr. Arnott's hydrostatic bed, and grateful and useful as it often proves, it is somewhat difficult to carry out in practice the principles on which it is constructed. For, to allow the patient to be supported entirely by the water, he requires to be immersed in it with the exception of the head and a small portion of the anterior part of the thorax: but any of the beds I have seen are not formed with a sufficient quantity of waterproof cloth, and consequently the patient is borne upon the stretched cloth, not floated in the water, and the pressure acting principally upon the tissues over the more prominent parts, as the points of the ilia, the trochanters, and sacrum, the weak vitality they possess is soon destroyed. Even when the bed is constructed according to the directions of the inventor, the mattress requisite to prevent subtraction of heat and communication of dampness by the cold water*, prevents perfect diffusion of the weight of the body, and the prominent points, as in the other case, soon give way: still, with all these objections, I believe the hydrostatic bed, as it is the most ingenious, so it is the best we possess for obviating injury from pressure†.

The means I used may have retarded the bad effects of pressure; they did not prevent or arrest them; and, all things considered, the only legitimate conclusion I can draw from experience is, that the utmost degree of quietude, on a plain firm surface, such as a hair mattress, which is compatible with the avoidance or retardation of sloughing, is the extent of our serviceable interference, in so far as relates to rest and posture, in the treatment of fractures of the spinal column.

It has been proposed to call in the aid of splints in this kind of injury; but when we reflect that they must be retained, supposing the fracture in the dorsal or lumbar vertebræ, by bands over the yielding abdomen, and would therefore be ineffective; or applied around the thorax, if loosely, useless, and if tightly, unbearable; and that their necessary hardness and firmness of application will of a surety hasten the sloughing, which the most appropriate measures cannot prevent; we must take leave, with all due respect, to dissent from the recommendation "that some sort of splint" should be applied "on each side of the spinous processes,"—an advice given with a vagueness not usual with the talented and experienced writer, Mr. Liston.* True, there are cases of fracture without displacement, therefore comparatively slight injury to cord, and only partial paralysis and loss of sensibility; but even in these we fear that pressure by splints, of sufficient degree to prevent motion, would, at the same time, be certain to occasion the serious evil of sloughing.

To relieve the pain in injured part of spine, and to prevent inflammation in the vitally important cord, I repeatedly applied leeches in two of the cases forming the subjects of this paper.

Among other reasons, the practice is objected to because it necessitates motion; and were all motion avoidable, the objection would be a valid one. But as the patient will, in all probability, require to be moved in order to prevent sloughing, advantage may be taken of it to apply leeches, if considered requisite. Were the practice of absolute necessity, contrivances could easily be had for its employment without change of position. Used in moderation, where there is no displacement,

* Dr. Arnott recommends a couple of folds of blanket, not a mattress.—Ed. GAZ.

† Air beds are now frequently used.

* Practical Surgery, ed. 1837, p. 52.

they should tend to prevent the destructive effects of inflammation, as softening, or effusion on the cord or membranes, and of ulceration and suppuration in the bones, ligaments, and intervertebral cartilages. In spinal fracture, with displacement, the principal cause of morbid action not being removable, the serviceableness of leeches is very limited, if not altogether doubtful; and if applied frequently, and in considerable numbers, I would fear increase of the disposition to sloughing, by their influence in diminishing the actions of the nervous and sanguineous systems. The difficulty of always deciding whether the paraplegia arises from fracture, extravasation, or concussion, will sometimes prompt us, in equivocal cases, to employ local depletion; and similar reasons may actuate us to exhibit, as I did, small doses of mercurials, which, in the one set of cases, would be highly proper practice, though in the other, viz. fracture, especially if accompanied with displacement, the propriety of using the mineral is, in consequence of its debilitating effects, somewhat more than problematical.

In the early stage we exhibited *Ol. Ricini*, with *Sp. Terebinth.*, to obviate the constipation and remove the tympanites. In the second stage, when debility had set in, and the rigors and perspirations indicated the supervention of softening and suppuration in the cord and surrounding parts, the peristaltic action of the intestines, mainly dependent on the organic nerves, were much increased, and causing, or accompanied by, augmentation of secretion from the mucous membrane, diarrhoea and dysentery became troublesome, and greatly accelerated the fatal result.

The principles of treatment deducible from the observation of my cases, and the reasoning founded on them, will be found expressed in the preceding remarks; and I will close them by acknowledging that, if of any practical value at all, they will be so, less by pointing out what will be directly beneficial, than by showing what will be hurtful, in the serious lesions existing in fractures of the vertebrae; that our treatment should be less an active attempt to control diseased conditions, than the employment of palliative measures, in order to afford nature

every assistance, by preventing additional involvements, and thereby limiting the necessity for, and husbanding, her restorative researches.

REPORT

ON THE

ROYAL MATERNITY CHARITY.

By F. H. RAMSBOTHAM, M.D.

(For the *London Medical Gazette*.)

[Continued from p. 369.]

DURING the year 1839, there were delivered in the Eastern District of the Royal Maternity Charity, under the superintendence of Dr. F. H. Ramsbotham,—

2079 women—Of which cases,

18 were twins—being one in every 115½ cases: of these in 9 both heads presented; in 6 the presentations were head and breech, or some part of the inferior extremities; in 1 both were breech or inferior extremities; and in 2 the head and shoulder. The children in 4 cases were both boys; in 9 both girls; and in 5 of different sexes.

1082 were males.

1015 were females.

2044 were presentations of some part of the head, of which 8 were face presentations—about one in every 274½ births.

48 were presentations of the breech, or some part of the inferior extremities—about 1 in every 43½ births; of these 8 were twins.

5 were transverse presentations—about 1 in every 419½ births; of these 2 were twins. All were at full time, and delivered by "turning." Three were still-born; one of these was a second child of twins.

In 5 the placenta was implanted over the mouth of the womb; 4 entirely and 1 partially—one in every 416 cases. All these women were delivered by "turning;" the head presenting above the placenta. Three of them died of the effects of hæmorrhage; one,—the case of partial presentation,—within half an hour after delivery; the child was dead; another on the eighth day; this child was born living; and the other in 8 hours; this was at 7 months: she had suffered severe hæmorrhage for three weeks, and the child was born still.

The other two women did well; but one of these children was also still-born; so that only two women and two children were saved out of the 5 cases.

7 were complicated with alarming hæmorrhage before delivery; *not* the result of placental presentation—one in every 297 cases. All these children were expelled naturally; and all were born dead; four of them were premature; in 1 case the feet presented, and the funis prolapsed; in another hæmorrhage had been going on for five or six weeks before labour commenced. All the women recovered; in all the artificial rupture of the membranes put a stop to, or much diminished, the discharge of blood.

In 14 cases the placenta was retained within the uterus, either by stony or irregular contraction of the uterine fibres, or by morbid adhesion between the uterine and placental surfaces, requiring the introduction of the hand for its removal—one in every 148½ cases. With all these there was more or less hæmorrhage. All the women did well. Two were twin cases.

2 were delivered by craniotomy—one in every 1039½ cases; they were neither primary labours, but in both cases the pelvis was distorted; in one there was a cicatrix in the vagina, the result of *eloughing* after a previous labour; and in the other the child was putrid, and had a tumor attached to the cranium.

3 were delivered by the forceps; one by the long, and two by the short instrument;—one in every 693 cases. In the case where the long forceps was applied, it was the woman's ninth child; she had always had lingering labours; the membranes had ruptured twenty hours before I saw her; the chief part of the head was above the pelvis brim, which was considerably narrowed in its conjugate diameter. The child was born living, and she did well. In another case the child was born still, and the woman recovered. In the third the child was born living; the woman went on very well for a week, when, owing to great imprudence, she was suddenly seized with violent inflammation, which carried her off in a few hours.

1 was complicated with puerperal convulsions before labour; she was seized in the night when she was alone, and found insensible in the morning by a neighbour; she continued in a

comatose state, with occasional fits, for twenty-four hours, when she was delivered naturally of a live child. She had been previously much relieved by bleeding and purging, and eventually recovered. This was her third child.

9 women died either from puerperal causes, or within the puerperal month—one in every 231 cases; 5 only, however, as a consequence of labour—about one in every 260 cases; for one woman was almost in the last stage of typhus when she was delivered.

2012 children were born living.

85 children were born still—one in about every 24½ births.

Of the Deaths,

3 were from the effects of hæmorrhage, under placental presentation—one within half an hour after delivery; another in 8 hours; and the third on the 8th day.

1 from hysteritis a week after delivery by the forceps. This was attributable distinctly to the woman's own imprudence.

1 on the third day after a lingering labour from "hydropic fever."

2 from peritonitis within ten days after delivery.

2 from typhus fever; one nine days, and the other a month after labour.

Of the still-born children,

21 were premature.

6 were putrid, at full time, or nearly so.

15 were presentations of the breech or some part of the lower extremities, at full time or nearly so.

3 were transverse presentations, at full time or nearly so.

With 8 the funis prolapsed.

1 was a face case.

2 were delivered by craniotomy.

2 were delivered by the forceps.

3 were delivered under placental presentations.

3 after violent accidental hæmorrhage at full time.

6 under lingering labour.

2 were the second children of twins.

1 woman was ill with fever.

2 had suffered an accident shortly before going into labour.

10 were at full time, not putrid, nor delivered by art; there being no assignable cause for the death of these children.

RECORD OF CASES.

By THOMAS MAYO, M.D. F.R.S.

Physician to the Infirmary of St. Marylebone.

(For the Medical Gazette.)

[Continued from p. 228.]

Phlegmasia Dolens.

PRISCILLA RANDALL, a healthy and well-made young woman, of a dark complexion and bilious temperament, had been delivered of a healthy child seven weeks before she was received into the Infirmary of St. Marylebone. Her confinement had been easy; her milk plentiful; so much so that she had assisted in nursing another infant besides her own. Her health since her confinement, for the first five weeks, had been good, except that her lochia had been very insufficient, or almost entirely absent. She first came under Mr. Stafford's care in the Infirmary, on account of pain and swelling of the knee: having remained under his treatment a week, she was transferred to my female ward on the 26th of June, 1843. I saw her on the 27th. Her expression of countenance immediately attracted attention. It was vacant, and at the same time excited—an expression which she retained until convalescence. She was constantly rolling about her head. Her eyes were remarkably protruded; the pupils somewhat contracted. Her manner was childish; her utterance very indistinct; but she seemed to endeavour to continue a rambling talk. She complained, as far as could be understood, that she lost her sight and recovered it again suddenly and at intervals. Her aspect did not at that time indicate severe disease. The skin was warm, pulse small and quick; right knee swollen and tender, fluctuation was not then observable in it. She was nursing her child, having plenty of milk. The bowels were described as being open. The resident physician had given her the Pil. Galbani Co. gr. v. 6tis., probably under a natural suspicion of hysteria; he had also prescribed an emetic, and the lead-lotion to the knee. I directed Hydrarg. Chlorid. gr. ij., Opii. gr. ss. 8vis. horis; and cupping to the nape of the neck ad 3viij.

June 29th.—The pulse had become more open, the aspect more composed,

the intermittent amaurosis had ceased, and the head rolled about less. The bowels had been freely opened on the 28th. The knee was more swelled; fluctuation evident, with extreme tenderness, and heat of surface. The right thigh had enlarged; it was hot; and the femoral vein could be traced down it, having a corded feel. The patient complained of much tenderness about two inches below the os pubis; the femoral artery was observable beating with great impulse, having no such impulse on the left side. She had been very restless during the night; her manner continued the same as above described.

I ordered 15 leeches in the course of the vein, and the calomel and opium to be continued 4tis horis.

30th.—The leeches had drawn blood freely; the knee was very red and glassy, but less tender; much impulse still in that femoral artery; the urine plentiful; the tongue dry.

Calomel and Opium were continued, and two ounces of aperient mixture (Sulphate of Magnesia and Infus. Sennæ Co.) were given.

At 9 P.M. of that day the bowels had acted freely, and the tongue become moister. But the face was then contracted and livid; the skin cold; the pulse small; the restlessness increased.

I gave Liq. Opii Sedativ. ℥xxx.; Potassæ Bicarbonat. ʒj.; Misturæ Camphoræ, ʒiiss. that night.

July 1st, 1 P.M.—She had slept, and looked better. The action of the femoral artery had diminished; the fluctuation at the knee increased. I directed that it should be punctured, and a free discharge of healthy pus took place.

The sedative was repeated that night, and the two next nights, and Calomel and Opium continued 8vis horis.

The corded state of the femoral vein, and the distension of the right thigh, now yielded gradually; but the rambling manner increased into delirium; the projected eye and contracted pupil became more marked; the pulse quicker and smaller; the cerebral symptoms thus appearing to increase with the remission of those of the knee and thigh, the size and tenderness of which were now completely reduced.

Leeches were now applied on the 6th, and again on the 10th, on the

shaven vertex of the head, where the heat was very marked.

Hydrag. Chlorid., Squills, and Pulv. Ipecac. Co. of each 2 grains, were given *8vis horis* from the 6th to the 10th; then *bis quotidie* to the 14th, when moderate salivation was established.

On the 15th, she had passed *faeces* in bed without notice, and continued to do so for some days. It was difficult, during this period of cerebral excitement, to prevent her getting out of bed, and wandering in the ward; she nursed her infant during the whole time with an ample quantity of milk.

On the 14th, a seton was ordered by me at the nape of the neck. From the time that a discharge from the seton commenced, the series of cerebral symptoms receded, and she continued with little excitement, no heat of head, a small but soft pulse of 100, to the beginning of August, the seton discharging freely.

The next form of symptoms that occurred was a highly congested state of the conjunctivæ of both eyes, with heat and pain. A collyrium of alum and zinc increased this; the application of five leeches removed it. These symptoms, I may observe, came on immediately on an attempt being made by me to give her a preparation of iron, which seemed indicated by her extreme depression of strength.

On the 9th of August I have recorded that she continued perfectly irrational, but free from excitement. Her strength had increased. Her manner at this time was very hysterical, laughing and crying without cause.

Her diet had varied with her symptoms, in regard to stimulants, but nutritious food in moderate quantities always had been allowed.

On the 11th of August, with no new medical measure, except the application of a blister, and immediately after this, the mind became much clearer, and more rational. The pulse fell to 80. The appetite and liking for food increased. This blister discharged very profusely. But with the return of her reason, and consequent efforts to help herself and her infant, another set of symptoms became obvious. Whether they had previously existed I am unable confidently to say: this was hemiplegia on the right side. And this has been the last development in the

succession of symptoms. From that time to the present day (Nov. 18, 1843), the patient has been in a state of progressive improvement, including a rapid diminution of the hemiplegia. The improvement has extended to her articulation, which, it may be remembered, was defective from the beginning of the disorder; though this latter state has been improving slowly, the use of her limbs having completely returned for some weeks. On the 12th of Sept. I commenced a course of strychnia, the 12th of a grain three times a day; during the last three weeks it has been increased in frequency. Its use was intermitted for about a fortnight, and we observed that on its resumption the power of articulation increased more rapidly. This medicine produced its characteristic spasms. The patient wears now the appearance of very good health.

Whatever hypothesis we may form respecting the causation of the above disorder, and its possible connection with suppressed or deficient lochia, as above adverted to, the succession of symptoms here observed deserves attention. At first, with some cerebral disturbance, which continued in various degrees through the whole case, a corded femoral vein, with white œdema of the thigh, inflammatory swelling of the knee, and excited action of the femoral artery. On the formation of pus in the right knee, the action of the femoral artery, and the corded state of the vein, was reduced. On the cessation of this process, the symptoms of cerebral turgescence became more obvious. On their abatement, contemporaneous with the action of a seton, the conjunctiva of both eyes became highly inflamed and painful. The state of hemiplegia next attracted attention, which certainly had not existed during the period of cerebral turgescence, heat, and fulness, under which the patient had walked firmly and steadily about the ward. Defective articulation existed throughout the whole progress of the case.

Now it is worthy of notice that the severe humoral disturbance which was present during a portion at least of this case, coexisted with mental symptoms and other evidences of nervous irritation, which might have given to this proteiform malady the name, and

assigned to it the *treatment* appropriated to hysteria, but for the obvious presence of that severe humoral disturbance. Even the care with which this person nursed her child, and avoided hurting it, during all the stages of the case, would have strongly favoured a suspicion of hysterical simulation, if definite symptoms had not evidenced the presence of inflammatory disease, however hysterical the diathesis of the patient. Perhaps I may adduce the readiness with which, on the 30th, the patient's strength gave way under depletion, as calculated to strengthen the imputation of hysteria.

The above views suggest the necessity of caution in our modes of applying certain very valuable doctrines of the present day as to the hysterical character of some local affections. For, whereas these doctrines tend to a soothing and tonic practice in such cases contemplated as hysterical, the narrative here given points out that the real disease may be, *not* an hysterical affection masked by an apparently inflammatory disorder, but an inflammatory disorder masked by the phenomena of the hysterical diathesis. An error of mischievous consequence may thus be induced in point of treatment.

[To be continued.]

ON THE DIVISION OF MEDICAL LABOUR.

By ROBERT HULL, M.D.

(For the London Medical Gazette.)

On the Army Surgeon.

SOME valuable letters have recently appeared on this subject. The medical men who are attached to the British army, furnish, undeniably, excellent models of therapeutic skill and gentlemanly bearing.

Surgery itself is heroic; concatenate with arms, it is peculiarly ennobling. In the most ancient and the most warlike times the army surgeon was held in honour.

Machaon and Podalirius are commonly imagined as the only medical practisers who accompanied the Grecian forces to the war of Troy; but, from a narrative in the eleventh book of the Iliad, it is clear that chirurgic officers were to be found elsewhere; for

Idomeneus is represented as sallying forth, during a smart engagement, in which a friend had received a wound, and been conveyed to his hospitable quarters; but he did not go to the field until he had secured for his confederate surgical aid:—

— δ δ' ἰητροῖς ἐπιτείλας
Ἦεν δὲ κλισίης—

The popularity of Machaon and his brother were due perhaps, in some degree, to their rank. They were general officers as well as medici, and furnished a large quota of fighting men. Look at the number of their transport vessels; according to the statement of Dares, "Podalirius et Machaon Æsculapii filii ex Tricā Navibus xxxii."

The honours paid to Surgeon Machaon are strongly depicted in the fourth Iliad. Menelaus is wounded, and his brother, the Commander-in-chief, dispatches an aid-de-camp to the great operator; he—

— finds Machaon, where sublime he stands
In arms, encircled with his native bands.
The heavy tidings griev'd the godlike man;
Swift to his succour through the ranks he ran;
Then suck'd the blood, and sovereign balm infus'd,
Which Chiron gave, and Æsculapius us'd."

But the general interest felt for Machaon is farther displayed in the eleventh book. Here Machaon himself is wounded; and so respected was this soldier-surgeon, that the oldest general in the army was requested to turn his war-chariot into an *ambulance volante*, and convey the wounded hero to the rear.

"To Nestor then Idomeneus begun;
Glory of Greece, old Neleus' valiant son!
Ascend thy chariot, haste with speed away,
And great Machaon to the ships convey.
A wise chirurgeon, skill'd our wounds to heal,
Is more than armies to the public weal."

Even Achilles, who was then labouring under a fit of the spleen—who, it was suspected, inwardly rejoiced at Grecian discomfiture—was touched at the spectacle of the wounded surgeon, whom Nestor was conducting.

"Go now to Nestor, and from him be taught
What wounded warrior late his chariot brought:
For, seen at distance, and but seen behind,
His form recall'd Machaon to my mind."

Patroclus, recognising the surgeon, exclaims—

"With grief I see the great Machaon bleeds."

It is impossible not to give the chirurgic warrior the meed of superior courage. The simple soldier has but general ideas of wounds and death. The anatomist, conversant with the machinery of the human frame, sees,

with his mind's eye, the infinite chances of dissolution. The layman calculates on the chances of escape; the heart and the great vessels, the brain and the big nerves, the hollow viscera, once opened, never to be closed, are, and must ever be, present to the military surgeon.

The tendency of anatomical knowledge is obviously to make the operator trepidant when his own fabric requires the knife. No men seek to avoid pain with more anxiety than those who professionally inflict it; but the warrior-surgeon, in spite of his professional trepidation, encounters the extreme of danger with the extreme of science and of courage.

The merit of those admirable men, who have in any, or in every, army performed their chirurgic duties within range of shot, exposed to the sabre and the bayonet, has yet to be recorded. Some distinct history is wanted of army-surgeons, which would be as interesting as it is demanded for literature.

In military practice the division of labour seems imperatively to be required. It has been asserted that he who operates on the wounded warrior is also the proper man to decide on healthy positions, on epidemic maladies, on corrupt provisions; that he must be a physician. But are not surgeons mainly required in the day of battle? are the men whose enthusiasm and prowess are chiefly medical the fittest ἱεῖρες for the great business of the Nile or of Waterloo? "We are not always fighting. None but mocks imagine the soldier with his sword ever unsheathed." This is true; but, as armies are expressly raised for fighting, surely when the business is begun, there are wanted the men of business—masters of surgery. The operations of civil life are performed at leisure, with friends and auxiliaries around, without distraction. The surgery of war is called for on a sudden, with infinite variations; for cases never detailed by the teacher, never exemplified in books: the operator must be independent, losing no time, fearless of personal mutilation, braving his own death. Deeply versed in anatomy, practised in operations, unterrified by blood—prompt, instant to repress it, through a knowledge of every artery, he must be not a doctor, but a deer.

The medical degree is no test of

handwork; it implies a preponderance of physic over surgical education; yet in our present Army Lists the physical diploma gives commonly a title to the regimental surgeon. I do not say that the Director's preference of this class of gentlemen is not, abstractedly, laudable, tending to raise, among the combatant officers, the medical character.

But, pleasant as may be the working of the system in the British forces, is there any fear lest, in civil life, the division of labour should be damaged thereby? lest the retiring soldier should carry with him his general practice, still using his physical degree? This remains to be shewn: as yet the system has not been tried long enough to prophecy its effects on civil practice; as yet, I believe, no harm has accrued, at least in England. The militant doctor, when he settles in social multitude, when no longer

— castra Juvant et lituo tribe
Permistus sonitus ———

practises as a pure physician. He concedes, as a gentleman, with the usages of the civil profession, exquisitely sensitive lest he should err in the slightest manner. He is, perhaps, a "Peninsular man," whose experience of grand operations gives him a just confidence that if he chooses to practise civil surgery, still sporting his medical prefix, he may realise a fortune. And why does he abstain? Because it would be irregular; hostile to discipline, which in the army he has admired and obeyed; hostile to the τὸ ὑπέρον; "shabby." Perhaps he fixes his abode in a provincial city, with a hospital in its precinct, of whose vacant offices he may have a choice, surgical or medical. Does he covet the chirurgical appointment, still maintaining his physician's title? No! Will he undertake, will he canvass for, the vacant place of physician, secretly intending to operate in private practice? Neither! a physician is he who practises physic. This latter situation is meant, in all hospitals, for the physician; that is, not for the general practitioner. A doctor who practises surgery is a general practitioner; and the soldier physician, not inquiring the readiest road to lucre, but what is expected from him as a gentleman, drops his lancet with his sword, and, in the hospital, elected physician, out of it he practises purely physic.

For myself, I entertain no fear lest

the military physician should lose his self-approbation, forget his delicate sense of honour, and usurp a position purely medical, unless his practice be that of purest medicine.

Years have elapsed since John Bell commended the army to the young practitioner as a school for polishing and dignifying the man; and every year's experience—peace or war, home or abroad—has verified the wisdom of his eulogy. Never, with such becoming examples of manners and conduct as our medical soldiers display, never would I second the effeminate cry—*cedant arma togæ*.

But, although the confusion of departments will not be produced by army physicians, it is occasionally created by men who have never been disciplined in camps, and the question has been put in some quarters, what is the professional etiquette due towards doctors who practise surgery? The question meets a more easy reply. They are general practitioners: and, whatever is the relation of these gentlemen, in that precisely they stand. There is but physic and surgery, and he who practises both is the general practitioner. "How!" exclaims the pert patronus of the London University, "I am a doctor medicinæ and a magister chirurgiæ!" Yes; and your rival is a Licentiate of the Apothecaries', and a member of Surgeons' Hall; you both practise generally. The College of Surgeons, the Apothecaries' Society, are amply competent to license the general practitioner: and when we meet with gentlemen endowed with their diplomata, we encounter men whose titles to confidence are known and legitimate: all other qualifications for general practice may be good, or may be insignificant. It is not what a man is called, but what he does. It is not academic honours—Blucher was an Oxford Doctor of Laws; so is the Duke. But they do not practise law. Their forte is the sword; and deeply do I wish that their triumphant victories over national irregulars could be imitated in our profession; and that every charlatan, ignorant or educated, were sent, as he ought to be, to the black-hole. The position of the doctor practising generally is that of the general practitioner; and, however the public may be mystified by such a personage, the profession has a clear duty to perform.

If the pure physician is requested to meet in consultation such an "hermaphrodite," called in "over him," he may decline a meeting with him as a general practitioner. If the pure surgeon is solicited to consult with him, his plea is the same; and if the plain general practitioner is expected to confer, he may reply, "The title of Doctor is nothing to me, Dr. Omnibus is no more than I am; if the case is medical, I will only meet a pure physician; but if the case be surgical, it is the pure surgeon whom I should wish to consult."

It is of no use to wink at the fact that this kind of spurious physician is becoming endemic. Diplomata are purchased for a song, in Germany, and their English buyers practise "generally" in cities and in villages. Even British degrees are disgraced in a similar manner; and it is time to let the profession—the public are as ignorant as possible—clear away the mist that surrounds the subject, and see that the practice makes the practitioner; and that they must treat the graduate like the plain man, if he generalizes. Above all, the laws of the different hospitals should define verbally what is meant by the term physician; for, although the meaning is understood by all governors, and respected by all fastidious candidates, it is certain that in some hospitals a general practitioner has walked into the pure physician's office—excluding more sensitive and more dutiful men.

But I repeat, that in these days of danger to divided labour, of danger to discipline, decorum, dignity, the army men are the very class from whom there is the least to fear, the most to hope.

But, whilst the civil practitioner is confident in the tact and conservatism of the military physician, he has a duty to perform towards his regimental brethren. If he thinks of his own peace and happiness, he should endeavour to subserve his professional brothers in arms. The Director-General has done wonders to secure their comfort, to maintain their dignity, to secure their efficiency, to advance their science. But they have their gravamina. One of them is their compulsion to make an official, an universal, a periodic *inspectio pudendorum*. This is a monstrous indelicacy; it is felt to be such: it is deprecated in private talk: it is *not* deplored at head quarters. A

civilian may fearlessly denounce what a soldier must not, through a sense of discipline, deprecate. But the man who has no further connection with the army than that of every true Englishman who admires and loves it, may with duty, as well as philanthropy, assert that the practice is a disgrace to our profession, an insult on human nature; and requiring no counter-argumentation, save the inborn feelings of our race; and if no better proceeding, such as severe punishment on discovery of concealed disease, can be invented, it is better to brave any consequences than oppose the natural, heaven-born sentiments, which, in every age and country, are respected.

Norwich, March 13, 1844.

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

Caloric: its Mechanical, Chemical, and Vital Agencies in the Phenomena of Nature. By SAMUEL L. METCALFE, M.D. of Transylvania University. 2 vols. pp. xix. and 1100. Pickering. (Third Analytical Notice.)

It rarely happens to us, in our critical capacity, to have a work which we cannot finish off at a single sitting. If our readers have followed us in the two notices of this work on Thermotics—the only one extant—we feel assured that they will not grudge us the space which we still find necessary to give some account of the author's views on the important subject of pathology. It is, after all, a thousand times more gratifying to our editorial feelings to have a book before us which we can laud heartily, and recur to again and again with renewed pleasure, than to find ourselves with inanity and imbecility upon our critical tormentors. We linger over this book of Dr. Metcalfe's loth to part, and must once more confirm our grasp of his hand for a moment, before we finally quit it, to show him in what estimation we hold his labours, and whilst we place before our brethren views that we cannot but consider of high importance to the progress and successful practice of our art.

The most important chapter in the second volume of the work is that which the author devotes to the obscure

phenomena of secretion, nutrition, and waste; regarded by Cuvier, Bichat, and others, as the greatest mysteries of the animal physiology. In accordance with his general position, that animal heat is evolved in the lungs, and not in the systemic capillaries, as supposed by many, Dr. Metcalfe maintains that a difference between the temperature of the arterial blood and that of the solids is absolutely essential to all the operations of the animal economy, and that without the perpetual transition of caloric from the one to the other, there could be no union of the blood with the several tissues of the body; that animal heat is no less the cause of nutrition and muscular motion than is solar caloric the cause of all the chemical and vital combinations on which the growth of plants depends; that as the power and velocity of a steam-carriage depend primarily on the amount of caloric imparted to a given quantity of water in the boiler in a given time, so is the locomotive power of animals determined by the amount of the same active principle that is imparted to the blood in the lungs, and thence to all parts of the body. Nor is it more remarkable that this should be so, than that the velocity of planets through their orbits, like the various transmutations which make up the drama of nature, should be, as they certainly are, directly in proportion to the heating influence of the sun (pp. 666—676.)

But as it is an invariable law of nature that the cause of force is expended in producing motion, the caloric which is employed in uniting the proximate constituents of arterial blood with the different organs, and in maintaining their healthy activity, is carried off and removed from the body with a rapidity corresponding with the energy of the brain, muscles, stomach, &c., until the vital affinities by which the molecules of the blood are transferred to, and kept in a state of combination with, the solids, are gradually diminished, and finally dissolved—when, having performed the office of renewing the structure and vitality of the different tissues, the said molecules successively fall from their places and are taken up by the lymphatic absorbents, which convey them to the general circulation, to be again renovated in the lungs, in which they were originally

formed, and thence finally removed from the system by the several enuncitories as worn-out materials; while their places are immediately taken by fresh organic particles, which are continually supplied from the living fountain of arterial blood. Thus we perceive that the vital energy of all the organs, or their power of resisting the laws of dead matter, depends on the rapidity with which their composition is renewed; which, in its turn, depends on the amount of caloric that passes through them in a given time: that it is because more caloric is received from the atmosphere, and more blood generated in the lungs of warm than of cold-blooded animals, that the composition of the former is renewed more rapidly, their organization more highly developed, and all the powers of life greater; that whenever the nutritive properties of the blood are so far impaired, by whatever cause, that it is no longer in a condition to unite with the tissues, and replace the worn-out particles with living ones, emaciation ensues, and all the powers of life decay (pp. 677-8.)

But to illustrate fully these new and curious views of nutrition, it would be requisite to extract the whole of our author's chapter on the subject; and to show the various applications of this theory to pathology and therapeutics would require a separate volume. In accordance with the foregoing doctrines, however, Dr. Metcalfe maintains that every action of every organ is attended with a loss of its vital heat, and of its substance, and that this is the reason why the brain, senses, and voluntary muscles, are exhausted by violent action, and even by moderate exercise, when their energy is not recruited by sleep; that the proximate cause of *fatigue*, *hunger*, and *sleep*, is, that the substance and vital heat of the body are expended more rapidly by exercise than they are renewed by respiration and nutrition; that it is owing to this expenditure of animal heat by exertion that the body is proportionally weakened and rendered more susceptible of disease from exposure to cold after fatigue than at other times; that the specific office of sleep is to restore the substance and vital energy which have been expended by exercise; and that the principal difference between them is, that during exercise the expenditure exceeds the

income; whereas during sleep the income exceeds the expenditure (pp. 883, and 942.)

"In the theory of nutrition," says our author, "is to be sought the explanation of the proximate cause of all diseases; for if the blood be the fountain of life, from which all the organs are immediately formed, it follows, that whatever impairs its natural properties, must derange the nutritive process by which the healthy condition of the body is maintained. Nor is it possible that disease of the stomach, brain, or any other organ, could exist for any length of time, while supplied with a sufficient amount of good arterial blood; because if the latter be sound and healthy, so must be its products. But when so far deranged that its power of uniting with the solids, and of maintaining the various secretions, is seriously diminished, a portion of the caloric obtained by respiration, that is, transferred to the solids during health, and employed in carrying on the functions, is given out in the free state, or rather accumulated in the blood, causing a preternatural elevation of temperature, and a corresponding loss of power in the general system. In other words, so long as the vital warmth received in the lungs is employed in combining the proximate constituents of the blood with the solids, and in elaborating the various secretions, the temperature of the body remains at the natural standard; all the functions are performed with pleasurable regularity, and there is no preternatural or morbid accumulation of heat. Here is a key to the whole theory of fever, which depends essentially on a diminution and derangement of the formative process, as shown by the rapid emaciation that takes place during its progress, and which always terminates on the restoration of secretion and nutrition." (p. 683-4).

With this clue, Dr. Metcalfe proceeds to give the rationale of fever, and all its leading symptoms — an achievement that has been regarded by many of the most distinguished pathologists as hopeless — chiefly owing, as our author thinks, to the unsettled opinions of the profession in regard to the mode in which animal heat is obtained in health; and more especially to the fact, that medical authors have almost entirely overlooked the *agency* of caloric in the economy

of animal life; as admitted by Drs. Southwood Smith, J. Johnson, Alison, Tweedie, Bright and Addison, with many other living writers. And Dr. George Gregory observes, that "if we cannot unfold the nature of the healthy vital actions, it is not surprising that pathologists have failed in explaining those which occur in disease." (*Theory and Practice of Physic*, p. 164). In the work before us, the author has established the fundamental doctrine, that *all the venoms or predisposing, and exciting causes of fever, (as indeed of all other constitutional maladies,) tend to diminish respiration, and thus to impair the vital properties of the blood.* For example, in all the higher animals, respiration is diminished by an elevated external temperature, which, also, tends to raise that of the solids nearly to an equilibrium with the temperature of the arterial blood; and thus to diminish the nutritive process, the activity of which is in proportion to the natural difference between the temperature of arterial blood and that of the solids. Hence it is, that although caloric is assumed to be the physical cause of all the vital forces, they are diminished by the not bath, and by the elevated temperature of hot climates. Yet the author maintains that in all cases of languid circulation there is nothing so efficacious and pleasant as the due and well-directed employment of that agent on which all the operations of life depend, viz. caloric. Dr. Metcalf has also shown that respiration is no less certainly diminished, and the natural condition of the blood impaired, by the depressing passions, mechanical injuries, &c., than by impure air, and improper or insufficient nourishment: in short, that every variety of fever is ushered in by either a deficient supply of animal heat by respiration, the abstraction of heat by external cold, (especially when combined with moisture), or its undue expenditure by exertion; and that both are the principal causes of constitutional diseases.

He then lays it down as an axiom that the first prominent link in the chain of morbid phenomena which constitute fever is what is generally called a chill, the most general exciting cause of which is external cold, after the powers of life have been weakened by some of the predisposing causes above enumerated.

The consequences of the cold stage are languid circulation, a small and feeble pulse, a pallid or livid hue of the surface, a shrinking of the features and extremities, a torpor of the bowels, a stoppage of perspiration, and a diminution or vitiation of all the secretions. Owing to the slowness with which the blood is sent through the lungs, and the diminished amount of respiration, the nutritive properties of the blood are still further impaired, and matters are made worse by the retention of the secretions. As the brain, spinal marrow, nerves, and muscles, are no longer supplied with good arterial blood, there is a loss of sensibility, impaired memory, confusion of thought, head-ache, and stupor, together with pains in the back and limbs, not unlike the aching sensations produced by the loss of animal heat from over exertion, or from sitting long in a cold room; but with this difference, that in the former case they are more permanent and difficult to remove, because owing to a radical derangement in the vital properties of the blood. And as the stomach is no longer supplied with good blood, the secretion of gastric juice is arrested, so that there is loss of appetite, nausea, and other gastric symptoms.

But as the process of breathing, although much impeded, is still carried on during the cold stage, and as very little of the heat has obtained employment in combining the blood with the solids, a stagnating ho secretion, and consequently the general power of life gradually accumulates until he not long a formed. The consequence of this augmented temperature is, that the action of the heart is increased, by which a larger amount of blood is sent through the lungs, and more caloric is obtained in respiration, than in the first stage. In consequence of which, as a measure, the vital properties of the blood, and the general power of life, are increased, and the secretions are increased, and the temperature of the body is raised. The cold stage is, therefore, a period of the fever, in which the powers of life are gradually accumulating, and the secretions are gradually increasing, and the temperature of the body is gradually rising. The cold stage is, therefore, a period of the fever, in which the powers of life are gradually accumulating, and the secretions are gradually increasing, and the temperature of the body is gradually rising.

continued fever, whether denominated typhus, synocha, plague, or yellow fever.

We regret that our limits do not permit us to give a further analysis of the author's pathological views; but those who are interested in the subject will find that he has, for the first time in the history of medicine, explained why in one case fever assumes the quartan type, in others the tertian, in others the quotidian, in others again the continued form; and why, in all of them, the duration of the cold stage is inversely as that of the hot. We would also recommend to the careful attention of our readers that portion of the work which treats of the influence of climate on the stature, form, colour, and general character, of the human race; especially the chapter on the manner in which diseases are modified by climate and season—a chapter in which some exceedingly important observations will be found on the rationale of pulmonary affections, the nature of malaria, and the general laws of epidemics. He has likewise offered some very original and striking remarks on the *modus operandi* of medicines, poisons, &c.; and, in his chapter on Diet, the reader will find a searching criticism of the doctrines of Liebig, some of whose views of respiration, nutrition, and waste, are powerfully controverted. We close this article with a few of Dr. Metcalfe's summary conclusions, contained in his concluding chapter.

1. That the primary seat of fever is not the brain, spinal marrow, ganglionic nerves, the solar plexus, the stomach and bowels, Peyer's glands, nor any other particular organ, but all parts of the body, and especially the blood, which is the life of the solids, as maintained by Moses, Hippocrates, and Harvey, the alpha and omega of health.

2. That the whole theory of medicine must be founded on a knowledge of the mode in which the animating principle operates in health, and of all the agents that diminish, augment, or in any way modify, the functions of respiration, sanguification, secretion, nutrition, sensation, and muscular motion.

3. That the celebrated *vis medicatrix naturæ* is only a general term, designating the natural action of all the

organs, and depends on the principle of life itself, which converts food into blood, fashions every part of the body, renews its composition when wasted by the actions alike of health and of disease, and which connects all the organs into one harmonious system, and maintains it in health through the long period of 70, 80, 90, or 100 years.

4, and finally, that when the science of healing shall have arrived at perfection, it will be found to consist chiefly in the art of employing those agents on which the operations of life constantly depend; in other words, in making the organizing principle by which the body is formed, the grand instrument of its preservation in health, and of its restoration when diseased.

In conclusion, and for our own part, we beg to recommend Dr. Metcalfe's work in the strongest terms, not only to our professional brethren, but to all who take interest in the progress of physical science. It is one the like of which only comes from the press at rare and distant intervals. Based upon the most comprehensive knowledge of all the phenomena of nature, it illustrates in the most admirable manner the simplicity and the harmony of the laws by which, in time, the Creator commanded the universe to appear, by which he fashioned its parts, and by which, in unabated force, he maintains them severally in their integrity. It is a work, indeed, of sublime scope, and, rightly taken, of the noblest tendency. It is the truest specimen, and most successful achievement, of that which the late Earl of Bridgewater had in view, when he left a sum of money for the purchase and publication of a series of treatises illustrative of the wisdom and goodness of God in creation. But it has the great advantage over any treatise which could be obtained under such circumstances, that it is not "written to order." It is the spontaneous effusion of the gifted mind, brimful of knowledge, and tintured itself with the hallowed fire of poetry. Whoever possesses the Bridgewater Treatises must add this work of Dr. Metcalfe as a kind of necessary complement to the series—as the crown of the whole idea.

Elements of Comparative Anatomy, designed especially for the use of Students. By RUDOLPH WAGNER, M.D. Professor of Comparative Anatomy and Physiology, Göttingen, &c. From the German by Alfred Tulk, M.R.C.S. (PART I. *Mammalia*. PART II. *Birds*.)

THE name of Rudolph Wagner is already familiar to the profession of this country, from the practical knowledge of physiology and comparative anatomy displayed in his valuable works on these subjects, one of which, the *Elements of Physiology*, has been so ably translated by Dr. Willis. The *Lehrbuch der Zoötomie*, or *Elements of Comparative Anatomy*, having lately arrived at a second edition in Germany, Mr. Tulk has been induced, from the high standing which the work has obtained in that country, to bring out the present translation, without making any alteration, or even adding any new matter to the original text.

The plan of publishing the work in parts, each complete in itself, is a very good one, and judging from the two parts which have already appeared, the style and views of the author are well carried out. We are fully satisfied as to the great utility of the work to anatomical students, and to recommend it to them and to the profession generally as one of the best text-books that has lately been published.

The next part of the work will comprise the comparative anatomy of the amphibia; the fourth part will take in the fishes; and the fifth and sixth will comprehend the avertebrata. The work is not only highly practical and full in its information on the interesting department of natural science of which it treats, but is also one of the cheapest of scientific publications. Let every student make this work the companion of the approaching holidays.

MEDICAL GAZETTE.

Friday, June 21, 1844.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

MEDICAL INSTITUTIONS BILL.

It is even as we ventured to surmise it would be in our last week's number:—

The Medical Institutions Bill, we are informed on good authority, will not be brought forward this session. This decision on the part of the Home Secretary we lament extremely. We should have been sorry, indeed, to have seen a measure for the regulation of the medical profession forced through the Houses of Parliament without the concurrence of the majority of its members; but the unsettled state of all our medical institutions at the present moment, makes us much regret that we are not to have an official announcement of the principles which Sir James Graham had thought of taking for his guide in remodelling them. Had the bill been only introduced during the present session, it would have been highly satisfactory to the profession. We should then have had ample leisure to consider and to canvass its proposed enactments; we should have had an opportunity of expressing an opinion for or against its several provisions, and we think that the majority of the profession would have been able to let Sir James Graham know what were its wishes, what it believed to be its wants.

This medical bill, however, is, after all, rather of a particular and private, than of a general and public nature; it is so, at all events, in reference to those who are already members of the medical profession; and we presume that the Minister and Parliament will be disposed to consider it in the same way as they do private bills. Its provisions must in the end, and to a very considerable extent, be made matter of arrangement among the members of the medical profession, and the councils and governing bodies of the Colleges to which they severally belong. The government, as it has the unquestionable right, so will it do well and wisely, to interfere to the extent that may be necessary to secure highly educated and competent medical advisers for the community; so much

continued fever, whether denominated typhus, synocha, plague, or yellow fever.

We regret that our limits do not permit us to give a further analysis of the author's pathological views; but those who are interested in the subject will find that he has, for the first time in the history of medicine, explained why in one case fever assumes the quartan type, in others the tertian, in others the quotidian, in others again the continued form; and why, in all of them, the duration of the cold stage is inversely as that of the hot. We would also recommend to the careful attention of our readers that portion of the work which treats of the influence of climate on the stature, form, colour, and general character, of the human race; especially the chapter on the manner in which diseases are modified by climate and season—a chapter in which some exceedingly important observations will be found on the rationale of pulmonary affections, the nature of malaria, and the general laws of epidemics. He has likewise offered some very original and striking remarks on the *modus operandi* of medicines, poisons, &c.; and, in his chapter on Diet, the reader will find a searching criticism of the doctrines of Liebig, some of whose views of respiration, nutrition, and waste, are powerfully controverted. We close this article with a few of Dr. Metcalfe's summary conclusions, contained in his concluding chapter.

1. That the primary seat of fever is not the brain, spinal marrow, ganglionic nerves, the solar plexus, the stomach and bowels, Peyer's glands, nor any other particular organ, but all parts of the body, and especially the blood, which is the life of the solids, as maintained by Moses, Hippocrates, and Harvey, the alpha and omega of health.

2. That the whole theory of medicine must be founded on a knowledge of the mode in which the animating principle operates in health, and of all the agents that diminish, augment, or in any way modify, the functions of respiration, sanguification, secretion, nutrition, sensation, and muscular motion.

3. That the celebrated *vis medicatrix nature* is only a general term, designating the natural action of all the

organs, and depends on the principle of life itself, which converts food into blood, fashions every part of the body, renews its composition when wasted by the actions alike of health and of disease, and which connects all the organs into one harmonious system, and maintains it in health through the long period of 70, 80, 90, or 100 years.

4. and finally, that when the science of healing shall have arrived at perfection, it will be found to consist chiefly in the art of employing those agents on which the operations of life constantly depend; in other words, in making the organizing principle by which the body is formed, the grand instrument of its preservation in health, and of its restoration when diseased.

In conclusion, and for our own part, we beg to recommend Dr. Metcalfe's work in the strongest terms, not only to our professional brethren, but to all who take interest in the progress of physical science. It is one the like of which only comes from the press at rare and distant intervals. Based upon the most comprehensive knowledge of all the phenomena of nature, it illustrates in the most admirable manner the simplicity and the harmony of the laws by which, in time, the Creator commanded the universe to appear, by which he fashioned its parts, and by which, in unabated force, he maintains them severally in their integrity. It is a work, indeed, of sublime scope, and, rightly taken, of the noblest tendency. It is the truest specimen, and most successful achievement, of that which the late Earl of Bridgewater had in view, when he left a sum of money for the purchase and publication of a series of treatises illustrative of the wisdom and goodness of God in creation. But it has the great advantage over any treatise which could be obtained under such circumstances, that it is not "written to order." It is the spontaneous effusion of the gifted mind, brimful of knowledge, and tintured itself with the hallowed fire of poetry. Whoever possesses the Bridgewater Treatises must add this work of Dr. Metcalfe as a kind of necessary complement to the series—as the crown of the whole idea.

seems absolutely necessary; the poor have now no choice of their medical attendant; he is the officer of the guardians of unions; and government must require of them that they select men with a certain amount of qualification at least. The institution or institutions into whose hands it puts the business of carrying out its intentions in this direction it may designate, and instruct as to its wishes; but we apprehend that the constitution and administration of those institutions, in so far as the privileges of their members are concerned, must be left for settlement among themselves. It would not do to treat the medical body as they do children, or as the drill-serjeant does a certain number of rank-and-file of raw recruits. The majority of the medical body must be carried along with the authorities, in order to give stability to any enactment in which they are comprehended.

Could we hope that our weak voice might reach the ear of the Home Secretary, we should entreat him to expose officially the provisions of the bill or bills which he thought of introducing for the regulation of the medical profession during the present session of Parliament. His only purpose, his only wish, must be to pacify us—if that be possible—and he can only succeed in doing this by carrying the men of highest acquirement among us along with him in his measures. We are all alike tossed upon a sea of uncertainty and doubt at present; we are like a convoy ignorant of signals, or having no commodore, some sailing east, and some sailing west, every one running foul of another, though all have it in view to steer for and attain the far-off haven at last. Let us have a clear perception of what it is proposed to do with us; and we have tongues and pens that will soon give Sir James Graham to wit as to the mind in which we receive his interference.

We have more than one article on the subject of medical reform in our portfolio, which we have been keeping by us until we saw whether we were to have the Minister's measure or not. Various sections or classes of the profession have also given utterance in our contemporaries to their sentiments on the subject. The articles alluded to we shall now publish, and by and by shall take an opportunity of collating all that has been emitted on the topic, and try if any thing like the will and wish of the majority of the profession can be elicited from the chaos in which it now lies involved.

CRITICISM.

How difficult it is to be just! See what the critic in a late No. of a respectable American medical periodical says, in reviewing a work of Dr. Chapman: "This is a work that belongs to the medical classics. Written in a precise, polished, and energetic style, this production can be read with the purest pleasure. How different are its pages from the diffuse, involved, obscure, and saturnine language of many medical authors!" This is plain enough; but mark what follows: "At the same time it is often amusing to see with what determined pertinacity our distinguished author *will invariably invert every sentence and all its subordinate parts!*"

Would our readers like a specimen of the work be-praised and be-damned as above? Here is the very first paragraph that is quoted—the italics are ours: "Certain climates and *locations* have great influence on the production of phthisis. It is undeniable that while the hyperborean and torrid regions comparatively escape this severe scourge, *it is* the medium *latitudes*, when moist and chilly, and especially *a residence in overgrown cities*, or along the sea coast, that *generates* the consumptive diathesis. The British Isles, *which answer to this description*, are singularly exposed to the disease; and London more than the smaller towns, *the country being much less so*, except on the margin of the sea." There are polish and energy, grammar and connection, with a vengeance!

But it is next to impossible to be just

in book and professional criticism. It is pleasant heartily to praise; but then there is so little opportunity for praising heartily—it is only now and then that we can diet upon pine-apple pie, and eat green peas at the rate of a shilling a piece—the price of course enhancing the savour immensely. Having occasion to find fault, it is also extremely difficult to keep within bounds—ink is a dangerous compound—gall and steel flow from the pen and enter the soul of perhaps a friend, without the hand that guides the implement taking note of what it is about; these steel pens, too, have “uncommon sharp points,” and we for our editorial part are resolved to lay them aside, save and except for quackery and imposition. We shall also recommend goose-quills to our critical friends henceforth. Quacks and impostors we shall hold up to scorn, and we shall treat them to steel pens; positively bad books we shall *denounce*; indifferent or unworthy books by professional brethren we shall *ignore*; good books we shall *analyse and laud*. Let our friends take this as the rule of our conduct in future.

ON THE USE OF THE SUPRA-RENAL GLANDS; AND ON FATTY MATTER.

THE following are some of the results of Mr. Gulliver's inquiries concerning the supra-renal glands:—

The secretion of these glands is characterized by an abundance of minute molecules, as described in his Appendix to Gerber's Anatomy, p. 103, et seq. These are analogous to the cytoblasts or nucleoli of various corpuscles or cells, analyses of which are given in Mr. Gulliver's Notes to Dr. Boyd's Cases, Edin. Med. and Surg. Journal, No. 156.

The molecules are often found in the blood; and very abundantly in the veins of the supra-renal glands.

The molecules appear to be free nucleoli or cytoblasts, concerned in the growth, nourishment, and probably the reparation of the tissues.

Accordingly, the supra-renal glands are very large, plump, and juicy, at that early period of life which is the most remarkable for activity of growth and nourishment, and for the production of new cells; so that, at the period in question, a vast quantity of the molecules is furnished by the glands.

The size of the glands is connected with the lean or fat state of the individual; hence they would appear to furnish fat. They are much larger in healthy well-nourished infants than in those in the opposite condition. The

same rule applies to adults. In emaciated subjects the supra-renal glands are dwindled as much or more, relatively, than the body; and in well-fed or fat subjects the glands are comparatively large.

Contrary to the general opinion (for example, of Meckel, Manuel d'Anatomie, par Jourdan et Breschet, tom. iii., p. 592; and Bichat, Anatomie Descriptive, tom. v., p. 462), the supra-renal glands are not more wasted in old age than the other organs; and in some mammalia the glands are larger in adults than in foetal and young suckling animals of the same species.

The identity of the molecules of the supra-renal glands with the molecules included in cells, and with the free nucleoli or cytoblasts, will be immediately seen by comparing the form, size, and chemical characters of all these objects, which are, in short, the same as the fatty elementary granules of Henle.

As the origin of a cell, and therefore of growth, reproduction, and reparation, is a minute molecule of fatty matter; so it is curious that there is a proneness to the formation of fatty matter in decay; in other words, there is a retrogression to the fatty state.

The molecular base of the chyle (see note to Gerber's Anatomy, p. 56, and Appendix to same, p. 89) is a congeries of the minutest oily particles; a similar particle, a little enlarged, and with an albuminous pellicle, becomes the seed, as it were, of a cell.

A fatty degeneration of the arteries is the common decay of old people. Fatty matter accumulates in the seminal tubes of aged subjects; it does so very remarkably in softened fibrine; in old blood clots, especially of the brain; in the dull brown coloured and emphysematous portions of the lungs of consumptive patients; in brown or lead-coloured consolidation of the lung; in old purulent fluid; and in many other cases, some of which are given in Mr. Gulliver's papers in the Medico-Chirurgical Transactions, Vol. 26; and Edin. Med. and Surg. Journal, No. 156. Finally, fatty matter is very abundant in crude and softened tubercle, a fact noticed by Dr. Charles J. B. Williams (Principles of Medicine, p. 305) as possibly connected with the greasy state of the liver in phthisis.

ROYAL MEDICAL & CHIRURGICAL SOCIETY.

Tuesday, June 18th, 1844.

THE PRESIDENT IN THE CHAIR.

Two Cases of Tubular Expectoration from the Bronchi in the Adult. By JAMES REID, M.D. Communicated by Sir James Clark, Bart.

THE author commences by observing that there are few cases of this disease placed on

record, either by foreign authors or those of our own country. Dr. Watson, in his lately published lectures, has mentioned two cases (one of which is detailed in this paper), and remarks that none similar had before fallen under his notice.

The author's first case was that of a lady, æt. 28, who had an attack of bronchitis in Dec. 1836, which yielded to the usual means, leaving behind, however, a chronic cough. In February 1837, after having suffered severely from a sense of suffocation, she coughed up, with froth and mucus tinged with blood, several arborescent membranous substances, resembling casts of the minute bronchial tubes. This substance continued to be expectorated for several days, to the great relief of the breathing. She had recurrence of these attacks five or six times, at intervals varying from one to six weeks. The patient became emaciated, her general health suffered, and there was great dyspnoea. A residence in Devon restored her; but on her return to London, in October, she had an attack of dyspnoea, much more severe than the former ones. This was followed by the expectoration of the arborescent substance in much larger quantity and of a firmer consistence than before. A discharge of blood always accompanied it, but never to much extent. The patient had no return of the complaint after this, but died in December 1841, of a disease unconnected with the chest.

The second case was that of a robust healthy man, in the prime of life, who had complained, for two years, of uneasy sensations about the throat and fauces, and of there being something which he wished to cough up. In April 1840 he had a violent paroxysm of coughing, lasting for half an hour, after which the voice remained husky, and there was a ringing cough, and a sense of uneasiness at the upper part of the sternum. He recovered from these symptoms, but had occasionally cough and expectoration of mucus. In Feb. 1841, a sudden and rather profuse attack of hæmoptysis came on without effort. It was, however, soon followed by a convulsive cough, when arborescent flesh-like substances were brought up with great relief. The patient was bled to fainting on the first occurrence of the hæmorrhage, and a moderate antiphlogistic treatment adopted. He soon recovered, but the hæmorrhage recurred, and several portions of tubular substance resembling plastic casts of the extreme bronchial tubes were coughed up. On Dec. 19th, 1841, this patient had another attack of slight hæmorrhage, followed by the expectoration of a large quantity of the tubular substance; and on four or five occasions during the subsequent ten days there was a return of the hæmorrhage, and various portions of tubular substance of different sizes were coughed up. In this attack

the treatment was not so active as before: expectorants, a light diet, and cooling drinks, were found sufficient. Up to the present time (nearly two years) there has been no return of the disease.

The author dwells at some length on the general character of the disease in question; he thinks the cause of it may be most probably a specific chronic inflammation of the mucous membrane, altering the natural secretion, and replacing it by one similar to that produced by serous membranes.

The *prognosis* he considers may generally be favourable, provided there be no complication; and also that the two larger bronchi be not simultaneously affected. Cases are alluded to from Tulpius, Morgagni, and De Haen, in which there was complication with phthisis, peripneumonia, and pleurisy.

He concludes by some observations on the *treatment*, and remarks that vigorous discipline does not seem necessary, and he thinks he fell into error in his second case.

He believes that general bleeding will seldom be required, and that only where there is congestion of the lungs. Mercury and iodine proved of little service in his cases; and he should in future be disposed to rely more on mild expectorants and a light diet than on an active treatment.

Dr. Copland thought it fair to say, that the cases described by Dr. Reid were not those of a new and but little known disease, as might be imagined from the introductory remarks of the paper; indeed, the author had himself disproved their rarity by the many cases which he had quoted from others in the body of the paper. The disease was in fact not very infrequent. Many cases would be found recorded in the various periodicals. While conducting a journal himself, several cases had been transmitted to him for insertion, and the affection described by Dr. Reid was always alluded to by those writers who specially treated of diseases of the bronchi, in evidence of which he might refer to the article Diseases of the Bronchi, in his Dictionary of Practical Medicine.

Mr. Lloyd rose, but gave way upon the Secretary calling upon Mr. Bainbridge to relate the particulars of a case from which a preparation on the table bearing on this subject had been obtained. It was taken from a female, who near the end of pregnancy was seized with symptoms resembling croup, of an acute character. She was bled to forty ounces, leeches over the throat, &c. and when apparently going on well, and while eating an orange, suddenly died from suffocation: one of the pips had passed into the larynx, and producing spasm of the glottis, had caused her death. The preparation appeared to us to show deposit of false

membranes over the larger and smaller branches of the bronchi to a very great extent.

Mr. Lloyd gave the history of two cases where tubular formations were discharged from the bronchi, in one of which he had the opportunity of witnessing its disposition to recur after the lapse of eight or nine years. He also alluded to the analogous formations from the mucous membrane of the bowels.

Mr. B. B. Cooper inquired as to the mode of recognising whether these membranes came from the large or small intestines.

Dr. Stewart had observed the occurrence in the bowels, and also a disposition to this membranous formation in the primary and terminal branches of the bronchi, in inspecting the bodies of persons who had died from fever.

Dr. Hocken related a case of retention of urine in a female, a patient of Mr. Whidborne, of Queen Square, in whom the mucous membrane of the tongue and cheeks became the subject of this membranous exudation in a remarkable manner, after the exhibition of four grains of calomel given in two doses. The patient, however, recovered in a very satisfactory manner.

A Member detailed a case where excrescences from the larynx produced symptoms that might easily be, and in fact were, referred to chronic croup as their cause.

The conversation on this case was terminated by Dr. Webster regretting the absence of the author of the paper, as it precluded the Society from obtaining any further particulars of the cases, and especially information regarding the state of the bronchi in the patient, who died years after from other causes; a circumstance which he thought very essential to the complete description of the disease.

On the Introduction of the Solutions of Lead into the Bladder for the Decomposition of Phosphatic Calculi. By S. ELLIOTT HOSKINS, M.D. F.R.S. Communicated by William Prout, M.D. F.R.S.

The object of this paper was to illustrate, by the details of six cases, the benefits which may be expected to arise from injecting weak solutions of certain salts of lead into the bladder, for the decomposition of phosphatic calculi, on principles explained by the author in a paper communicated last year to the Royal Society. These salts act in destroying the concretions, by a process of double decomposition; whereby the active agent of the decomponent is liberated gradually, and neutralized by the earthy basis of the calculus, before it can come in contact with the living tissues; and the solutions are therefore easily borne as injections by the coats of the bladder. The salt which he first employed was the nitro-saccharate of lead, but he has

since substituted the acetate; and he describes the particular mode of using it.

The experience of the cases which he records, establishes, he thinks, two facts; first, that the presence of the injection is tolerated by the bladder, and that it even acts as a sedative, besides coagulating the mucus, so abundantly formed in these cases, into short curdy flakes, easily passed through the urethra; and secondly, that a chemical action takes place on the calculi. He believes that where surgical operation is inadmissible, this plan of treatment will be of avail, for relief, if not for cure; for smoothing away asperities, and removing the outward phosphatic coating of calculi, so as to bring them within the range of the crushing forceps; in short, for partial, if not for entire disintegration. The latter, he thinks, is more likely to happen, when layers, composed of the urates or oxalates, are bound together by phosphatic cement. He also directs particular attention to one of the cases, where a considerable quantity of calcareous matter was removed from the prostatic portion of the urethra, by the injection acting on calculi which were found lodging in that part.

Mr. Solly had had a patient under his care in St. Thomas's Hospital, upon whom he had tried Dr. Hoskins' solution, but without success. The bladder was so extremely irritable that it would not bear the solution. He had subsequently tried the nitric acid, and with somewhat better effect. By keeping the patient extremely quiet, and directing all means to allay general as well as local irritability, the patient at length gained such a state of health as permitted Mr. Solly to undertake lithotomy with a chance of success. The patient made a good recovery.

Mr. Lloyd expressed the pleasure he felt in being able to corroborate Mr. Solly, for he believed he had himself seen the case. It certainly was an extremely bad one, and one in which recovery from the operation reflected great credit on that gentleman.

Dr. Willis, although favourable to the use of solvents, believing, on chemical grounds, that they ought to succeed, nevertheless owned that the conclusion to be drawn from Dr. Hoskins' cases was, that we were still without efficient means of dissolving a stone in the bladder. Solvents for the phosphates, too, however necessary, were the last element that would be required to rid the bladder of a calculus; having dissolved the outer phosphatic layer, we should still generally find ourselves with a central mass of uric acid or oxalate of lime to deal with. He alluded to the powerful affinity of the earth lithium for uric acid, as a new means of attacking that substance. He also thought these cases of

Dr. Hoskins calculated to throw light on another point in the treatment of stone—the value of lithotripsy (a certain number of Dr. Hoskins' cases had been subjected to lithotripsy); used in proper cases, where the stone was small and the bladder healthy, lithotripsy was very valuable; used indiscriminately, it was improper.

Mr. Charles Hawkins spoke of the great value of lithotripsy, even as a general means of treating stone in the bladder; there was scarcely any case in which it was not applicable, and in private practice he had seen it all but invariably successful. He had had extensive opportunities, in private practice, and whilst assisting Sir Benjamin Brodie, in observing the powers and safety of lithotripsy. He related a case in illustration of what he had advanced. The average number of operations or sittings in each case was about three.

Mr. Bransby Cooper held that the test for the applicability of lithotripsy was the capacity of the bladder to bear the injection of from six to eight ounces of water. If it would stand this, the size of the stone, he thought, was of less moment. He certainly could not speak in the same terms as Mr. Hawkins either of the almost uniform success or safety of the operation of lithotripsy.

To the Editor of the Medical Gazette.

SIR,

AMID the various epidemics that sometimes attack the medical world, there is one that is conspicuous at present—I mean the *cacoethes loquendi* in young, and also in some few oldish men, particularly at the Royal Medical and Chirurgical Society. I would by no means inhibit the younger members from partaking altogether in the discussions, but I would ask them to recollect that in this Society members meet together to interchange matters of experience, facts collected from mature observation, and not to detail epitomes of the last night's reading, or cases little or nowise relevant to the matter under discussion, but only calculated to set off their successes and superior science. The evil is a double one; not only is the Society's time wasted, but many of the most eminent members are prevented from speaking. The character of the Society will certainly suffer if its discussions are allowed to become so trivial as they occasionally are, without comment, and the Fellows, unadmonished by the Chair, are permitted to talk from the point by the half-hour together. Why, finally, will two or three members, old enough to know better, insist upon offering their opinion upon every subject that comes before the Society? Now and then they would be listened to with patience; upon their legs, not once, but

twice and thrice in the course of the same evening, they become unmitigated bores: the Society should get its coughing apparatus into order, and give these gentlemen a significant sign of its discontent.

I have the honour to be, sir,

Your obedient servant,

SILENTIA.

June 11, 1844.

CURE OF EMPYEMA,

BY PARACENTESIS WITH THE TROCAR, FOLLOWED BY LATERAL INCURVATION.

By DR. GADECHENS, of Hamburg.

ADOLPH SCHARF, a strong boy, aged 3 years, who had suffered from hydrocephalus when he was a year old, and, though long ailing afterwards, had got into good health during a twelvemonth past, was upon the 29th November of last year seized with symptoms of catarrhal fever, to which supervened in the following days oedematous swelling of the face and the signs of pleurisy of the right side. On the 2d December the presence of a liquid exudation in the right cavity of the pleura was cognizable by the stethoscope. This extended nearly as high as the nipple, and occasioned considerable oppression, a dry painful cough, and violent sthenic fever. It seemed to have proceeded from cold. On more minute examination upon the following day it was ascertained that the right side of the chest was enlarged half an inch. The dull sound on percussion, the deficient respiratory murmur, the oegophonic tone of the voice on the diseased, and the perile murmur of the healthy side, left no doubt as to the existence of a considerable effusion. Notwithstanding the employment of antiphlogistic measures, the effusion increased; and the fever did not go away, but recurred every evening for some hours, with exacerbation of all the other symptoms. The respiration continued embarrassed; a short dry cough harassed the child at night, only quieted by opium; the skin was dry and harsh: the urine, scanty and red, deposited when cold a brick-dust sediment. The digestive powers were gone, and the strength was rapidly failing. Diuretics and tonics were tried for some time, with a little benefit, especially that of somewhat improving the health. The dilatation of the affected side, however, amounted to three-quarters of an inch. The annoyance caused by the effusion was now chiefly felt a short time before dinner; the breathing was proportionately less short in the mornings and evenings, and the cough less troublesome, so that the nights were quieter. On the 24th January it was decided in consultation that Dr. Wasmann should perform paracentesis. He accordingly passed a small trocar betwixt the

fifth and sixth ribs, about three inches outwards from the nipple, and by the canula thus introduced free issue was given to a considerable quantity of pus of a greenish yellow hue, and tolerably thick consistence. As soon as the discharge nearly ceased, and while, during a fit of coughing, a little air had penetrated with audible sound into the thoracic cavity, the canula was withdrawn, the wound dressed with adhesive plaster, and a bandage brought round the chest. The mother was recommended to get the child to lie as much as possible on the diseased side, in order to favour the efflux of pus. From eight to ten ounces of matter came away by the puncture, and a little more drained off in the course of the next eighteen hours. The wound now closed, and was found completely united at our visit of the 25th January. Immediate relief was obtained by the operation, as manifested by the freer movements of the chest, and the less short and frequent inspirations. Towards evening there ensued a febrile movement, with violent cough. Opium, however, as usual, did not fail to sooth, and procured undisturbed sleep during several hours. On the day following, stethoscopic research proved the fact of a partial dilatation of the compressed lung. Even under the site of puncture a pretty distinct respiratory murmur was audible, and percussion yielded a less dull tone in this region than formerly. There was no longer any evidence of the presence of air in the chest.

From the period of the operation, indeed, a notable amelioration was visible in the state of the patient, which daily made progress. Most striking was the effect of diuretic medicines. The urine directly became clear, lost its red sediment, and was much augmented in quantity. At the same time the distress of breathing, the oedema of the face and feet, the frequency of the pulse, the evening febrile exacerbations, all abated. Ere long the nights were spent in uninterrupted sleep, the skin assumed a moister and more natural feel, and the bodily vigour rapidly increased. The cough alone remained, and this we ascribed to adhesions. The stethoscopic signs on the 14th day after the operation indicated complete absorption of the effused fluid, and a corresponding dilatation of the compressed lung. Things went on favourably, the boy improved both in appearance and in strength, but in the course of a few weeks a marked deviation of the spine towards the sound left side was perceptible, with simultaneous flattening of the right thorax, constituting permanent scoliosis, a very unwelcome but unavoidable result of the cure of empyema. — *Oppenheim's Zeitschrift*, Dec. 1843, p. 540.

THE MODERN METEMPSYCHOSIS.

"WELL, and the souls of unworthy practitioners, what becomes of them?" It was thus that I was interrupted in the exposition of my system of cosmogony by my friend Bennet; and I will own I was gravelled by the question; for I found these souls even as difficult to dispose of in the other world as they are in this, and in my system of cosmogony I had not thought of the destination I should give to the souls of ignorant and unworthy practitioners of physic, of charlatans, and of those who live upon the credulity of mankind. But in a true system—and I hold mine to be incontestible—all the details come with the aid of a little reflection to range themselves harmoniously together; and having rubbed my brow for a moment, and scratched my ear, I delivered myself thus: The souls of unworthy practitioners, my dear Bennet, pass into the bodies of the animals which M. Magendie tortures and cuts up alive in his physiological experiments. This expiation appears to me most logical and legitimate; you may be certain that the dog whose sensible nerves the professor of the College of France is now busy pinching and pulling, the rabbit whose spinal marrow has just been exposed, and the guinea-pig whose chest, laid open, permits the palpitation of the heart to be seen, were so many unworthy practitioners of the bygone ages, who now expiate their barbarities, their effrontery, and their cupidity; all their cries of suffering are but accents of contrition and of imprecation vented by their souls upon the rack. Ah, Messieurs les Charlatans! you that were and are materialists, without faith, without religion, without morals, without probity, because you acquired ample riches by indefensible means, and enjoyed your good fortune grossly, you thought yourselves beyond the reach of punishment! No, no, sooner or later, one day or another, frog or salamander, guinea-pig or dog, your feet nailed to the table, another Magendie will hold you under his scalpel, will pinch and irritate your nerves, cauterize your plexuses, pierce your ganglions, and galvanize your muscles! And you, gourmand, you that make a god of your belly, to which you sacrifice all that is noble in human nature, beware! I see another Orfila in perspective infusing some abominable drug or deadly poison into your stomach, tying your oesophagus, and, watch in hand, counting the minutes and the moments of your tortures! Beware, I say!—M. Raimond, in *Gazette des Hôpitaux*, No. 65, 1844.

SUBSTITUTE FOR COD'S LIVER OIL.

M. F. DUBOIS, of Tournay, has lately substituted the simple, sweet, poppy oil, for the disgusting, stinking, cod's-liver oil, in the

treatment of strumous and rachitic diseases. He orders it in the same doses as the cod-liver oil. One important observation made by M. Dubois, without his apparently perceiving its application, is this: "It is proper to undertake the treatment of these diseases as much as possible in the summer season, for they yield much more readily than in the winter and spring."—*Ann. de la Société de Médecine d'Anvers.*

CANCER.

THE treatment of this disease is null at the present period. Surgeons operate; and when patients refuse to submit to the operation, they tell them there is nothing else for it. However, all agree that the operation does not cure; it does not even prolong life. Subjoined is the proof:—

From a return addressed to the Academy of Sciences by M. Leroy d'Etoilles, it appears that out of 1192 patients who had not been cut, 18 lived more than thirty years from the commencement of the disease; while of 801 who had been operated upon, 4 only were living after the same lapse of time.

There survived from twenty to thirty years after the development of the disease, 18 operated, 34 not operated; from six to twenty years, 88 operated, and 228 who had not undergone any operation.—*Tanchou, in Comptes Rendus*, 6 Mai, 1844, p. 879.

CUVIER.

FREQUENTLY *absent*, as we say, in the midst of his family, its members always made war upon the philosopher on these occasions. It happened particularly that he showed himself more than usually absorbed in his own reflections at the period when he was engaged in assigning to precise species the fragments of the fossil bones discovered in the quarries of Montmartre. He once in particular spent several days searching after the fore foot of a certain skeleton of which he had already collected numerous fragments; ever afterwards, when he fell into one of his absent moods, Madié. Duvancel would rally him, and giving him a gentle salute, would say, "Well, and art thou still seeking after that fore foot of thine?"—*Bourdon, Illustres Médecins.*

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

Gentlemen admitted Members, June 7.—A. Roberts.—G. J. Rose.—R. C. Griffith.—H. J. Domville.—H. Buck.—J. F. Cartner.—A. Hensfrey.—F. W. Marshall.—G. P. Hubbard.

ON HYDROPHOBIA.

*The Substance of a Clinical Lecture given at
St. George's Hospital, June 28, 1844.*

By **CÆSAR HAWKINS, Esq.**
Surgeon to St. George's Hospital.

I PROPOSE in to-day's lecture to bring under your notice the remarkable and rare disease, **HYDROPHOBIA**, a case of which you have recently seen; not, indeed, under the idea that it may prove of great practical importance, for as none of you, I believe, have ever seen the disease before, so it may happen that you may never see it again. It is now just twenty years since a case of hydrophobia was admitted into this hospital; and there have been only two cases since I first knew the hospital, twenty-five years ago, one of which occurred in the year 1823, when I was house-surgeon, under the care of Sir Benjamin Brodie; and the other under Mr. Jeffreys, I think in the following year, 1824. But although rare, it is right that you should be acquainted with the subject; and I will therefore make some remarks while the case is vividly impressed on your recollection. Certain I am, that having seen this case, you will never fail to recognise the disease, if you should again witness it, and that you are not likely to mistake any other malady for it, although there is no doubt that many of the cases related in medical works have been thus mistaken, several of the supposed cases of the disease having in reality been instances of some other spasmodic disorder, of which dysphagia formed a part. I will first read you the entire history of the case from the note-book, as far as the facts have been ascertained relating to it.

Charles Havens, 13 years of age, was admitted into the hospital in the evening of June 11th; and it appears that on April 22d, just fifty days previously, he had been

bitten by a dog on the right hand. The wound was small, and healed in three days; and there has been no fresh inflammation since that time; neither has he had any pain running from it to the trunk, nor is there any redness or soreness of the part. At the carpal extremity of the right thumb there is a small elevated cicatrix, with a scratch on each side of it. He complains of pain in the shoulder, from a fall three days previously to his admission. He remained well till this morning, the 11th, when he complained of feeling ill, and as his mother was washing him, he allowed her to wash his hands; but when the water was about to be applied to his face, he ran away with dread, and frequently placed his hand to his mouth, saying he was going to be choked. He was taken to a surgeon, who gave him an emetic. All this was not known when he was brought to the hospital at 9 P.M., at which time he is said to have had a furred tongue, a hot skin, and quick pulse, and some redness of the fauces, with slight difficulty in swallowing. Some calomel was given to him, and some senna ordered; but as he had two motions after the calomel, the senna was not given.

The next morning, the 12th, the notes say he had no sleep during the night; and this morning he is much distressed, and his countenance expressive of great anxiety at any surprise, or noise, or on any one approaching him; the least breath of air, the noise of water, and especially the sight of it, or the idea of swallowing, brings on a violent spasm of the muscles of the throat, particularly of those connected with the function of deglutition; and he complains of great pain in the throat when he attempts to swallow, which is done convulsively and with effort. It was while things were in this state that I was sent for, and I saw him for the first time between 9 and 10 o'clock.

About 10 A.M., after much coaxing, he swallowed a pill with one grain of Cannabis

Indica, said to be quite fresh; and at 11 A.M., an hour afterwards, another grain was administered. Some ice was also given him, but he could not put it to his mouth; "it took his breath away." The motion of the bed-clothes brings on spasm, and he holds his hand violently to his mouth whenever the door is opened, or there is the least current of air; he complains angrily also if any one brings his hand near him, whether towards the face, or even any part of the bed. The spasms of the throat are more frequent. His intellect is unimpaired. The pulse is about 90, intermitting irregularly, about four times in a minute—I should observe, however, that this was noticed earlier in the morning, before any medicine was given him. The fever of the night before was now nearly gone, and the redness of the fauces was no longer perceptible in the degree previously observed. At 12 o'clock, being in the same state, with apparently no effect from the pills, three drops of Scheele's Prussic acid were given, and the same quantity half an hour afterwards. At 2 P.M. you all saw him with me, and might have observed the symptoms before mentioned. The notes continue:—No apparent effect from the medicine; perspiration breaking out; spasms of the throat as frequent as ever; terror as great. A little beef-tea was offered him, and after much persuasion he took it up (insisting on a smaller quantity being given), threw it into his mouth, and instantly gulped it down; this was followed by spasm and great distress. There is now some wandering and confusion of thought, and he fancies he sees things and persons on the walls and around him. Two grains more of the hemp were administered, and the same dose was repeated at 3 and at 4 P.M., at which time the notes say there is more wandering; spasms of the throat not so violent; some perspiration. A beef-tea injection was about this time attempted to be thrown into the bowel, but he resisted so violently that it had to be given up; and the horror produced by the attempt remained for a long time afterwards. I saw him about 5½ P.M., still exceedingly alarmed at the idea, fighting furiously with his hands and whole body, and confusing in a singular manner the supposed shooting of the syringe with imaginary shooting in a shooting-gallery. Two grains more of the Cannabis were given at 5½ P.M.; and as the house-surgeon, Mr. Cundy, seemed anxious to apply a cloth dipped in laudanum and æther, which he had been informed had recently been done in two cases successively of tetanus, with presumed good effect, as both patients recovered, I gave him leave to use it; but the application had the effect of making the patient worse for a time. At 7½ P.M. there

was less spasm, but foaming at the mouth was now noticed, and violent mania, and he refused to take his pill; three drops of hydrocyanic acid were therefore given in its stead. He took a two-grain pill, however, at 8, and at 9, and again at 10½ P.M., at which time he was much freer from spasm, and had sucked an orange and taken a little beef-tea; but he wandered and talked incessantly. At 12 P.M. he took three grains of the hemp, and the same quantity at 1 A.M. At 2 A.M. he took two grains, and the same at 5, 7, and 8 o'clock. At 8 A.M. of the 13th, the notes say:—between 1 and 2 o'clock he had several fits of spasm of the throat, and two of these fits were accompanied by opisthotonos, each lasting about a quarter of an hour, with twenty minutes interval between them; since which time he has been more quiet and collected, and free from spasm and alarm, and continued so till 7 o'clock. During this time he took three eggs, with some bread and butter, and a little beef-tea, without apparent difficulty; he also talked sensibly, and once he appeared to sleep for a few minutes. The pulse is however weaker, his expression is more careworn, and he has some retching. At 9 A.M. he took three grains more of the hemp, and again at 10 the same quantity, at which time he was more violent, and refused to take anything else: he talks incessantly; the pulse is weaker, and the extremities are becoming cold; the eyes are hollow and staring; the expression of the countenance is horrible. He is now perfectly delirious, talking, singing, and shouting; he is vomiting constantly black matter, which he brings up with hiccough; there is heaving of the chest, but not much difficulty of breathing. At 1 P.M. he is furiously delirious, but evidently weaker; pupils dilated; eyes wild and prominent; mouth constantly filling with thick dark-coloured foam, which he spits out, and snatches with his fingers, and throws about him, and on those around him. The extremities are colder, and the hands more blue; the pulse is not perceptible at the wrist, and the heart's action is exceedingly feeble. There have been no spasms since 9 o'clock; he became gradually more feeble; the inspirations were finally not more than two or three in a minute; and he died calmly, and without further struggle, at 2 P.M., little more than fifty hours from the first time that any spasm was observed.

Such, then, is a full account of a case of hydrophobia, and it presents you with the ordinary symptoms of the disease. This is, I think, the tenth case I have myself seen, and they have all agreed in the main features, with some little variations in minor points.

In this case the actual hydrophobia, or dread of water, was very great during most

of the time; but this horror is by no means constant, and forms no essential part of the disease; I have even seen patients glad to swallow frequently, with much effort and exertion of the will, it is true, but still they did it on account of the comfort they derived from the act, probably by washing away the viscid secretions of the throat. The spasms, as you saw, were principally of the muscles of the fauces, throat, and neck, and are generally confined to these parts. In this boy they twice affected the muscles of the back; and in another case which I saw, the hands were contracted as in chorea; but the extension of spasm below the neck is accidental. You saw in this case, as a very prominent symptom, a very curious delirium; and the violence of action of this boy was as great as I have almost ever witnessed. More or less delirium is, however, always present; at least I have always seen some wandering; it may be of a pleasing kind, judging by the nature of the conversation, and the smiles I have seen, in one little boy whom I nursed from the beginning to the end of the disease; and it was so quiet, that he could always be roused from it to answer rationally. Even then, however, towards the patient's death, the same horror came on that Havens shewed, and the child buried himself in the clothes, and held out his hands to protect himself from imaginary dangers. On the other hand, the delirium may be most furious. I remember a case in one of the hospitals (Guy's, I think) where every body was glad to run away and lock the door on the patient to protect himself; and the man broke the window and railings and got out, and was with difficulty secured again. More or less delirium is, however, I repeat, always present as far as I know; and I dwell on this marked symptom, because I have been informed by one of you that a physician has remarked that he has seen seven cases of hydrophobia, in none of which was there delirium; leaving it to be implied that the Indian hemp might have produced it in our present case, as it is a common effect of that medicine. I have just looked at the notes of a good many cases, thirty-five, I think, of hydrophobia, and in only one do I see it stated that the patient never lost his senses, while delirium is mentioned in all the others; but in this very one the patient is said to have run away from his doctors and escaped into the village, frightened at the gargling of some injection that was administered to him, which is not quite the action of a person in his senses; and a strait waistcoat was used afterwards for the patient, who is said not to have lost his senses. The delirium of hydrophobia is exactly like that of mania, so that the patients will sometimes not know their relations, and will take

a fancy in favour of or against particular individuals. A little child of four years old would not allow a particle of clothing to cover him; and patients constantly fancy that insects or other animals are present, and will sometimes shew the most violent irritation at imaginary or real objects: for instance, a man with hydrophobia lay not far from a really insane person, who uttered frequently a particular word, "sharp," at which the hydrophobic patient was so offended, that he threatened to tear him piece-meal for doing so. There is often, as in this case, a remission of the symptoms in the last twenty-four hours, so that the patient can eat and drink without difficulty, and lie quiet and free from spasm; and you must not, therefore, always attribute this temporary quiet to medicine; fresh symptoms afterwards come on, as they did here, and are fatal. Then, again, you observed the vomiting of dark matter, and the spitting the thick mucus from the mouth, which are always more or less present, and have nothing to do with the medicine taken into the stomach, as the appearance is nearly the same whatever remedy is used. Lastly, you saw the mode of death, which is the common one; not by suffocation, but by gradual failure of nervous power, and of the heart's action, rather than of respiration.

I will next read the account of the post-mortem examination.

There was a small quantity of serum in the spinal canal both in the upper part of the cervical region and in the lumbar region, the membranes and cord being apparently perfectly healthy; the posterior spinal veins were less turgid than in many cases, although the body had been lying on its back since the death of the patient. The membranes of the brain were apparently healthy, and there was no effusion in the arachnoid or sub-arachnoid cellular tissue. Both substances of the brain were, throughout their whole extent, congested, and of a darker colour than usual; the grey matter presented a marked pinkish colour, especially that portion which was in contact with the pia mater. The ventricles did not contain more fluid than natural. The cerebellum, pons Varolii, and medulla oblongata, were congested, and of a pinkish colour, but these appearances were not more marked here than in other portions of the brain. The substance of the medulla oblongata was carefully examined in the microscope by Mr. Toynbee and Mr. Hewitt, but presented nothing remarkable. The different parts of the brain were somewhat softer than usual, but this softness was general, and most probably attributable to the time of the patient's death, and the state of the weather. The mucous follicles at the base of the tongue were very large and numerous, and

the mucous membrane of the fauces and pharynx congested, and of a dark venous colour—the discoloration did not extend beyond the level of the superior margin of the thyroid cartilage; below this the mucous membrane of the pharynx and œsophagus was of its natural colour; the mucous membrane of the windpipe was but slightly congested, and there was no thickening of the submucous tissue of the larynx.

The right lung was universally and firmly adherent—of course from old disease—and both lungs gorged with blood, but without serum (that is to say, there was not the discharge of serum into the air-vessels to relieve the overloaded bloodvessels usually seen in any form of suffocation), especially at the back part, where they were very soft, and of a dark colour. A few scattered tubercles were found in the right lung; the submucous membrane of the bronchi was slightly congested. The heart was natural, the blood contained in its cavities being small in quantity, very dark and thick, and with one or two small loose coagula, also of a dark colour; they presented no remarkable appearance in the microscope.

There were some small circumscribed arborescent congestions in the immediate neighbourhood of the œsophageal region of the stomach, and no other apparent lesion of this organ; these spots appeared like ecchymoses in some parts, but it did not seem that there was really any extravasation of blood. The liver, spleen, kidneys, and intestines, were congested, but otherwise healthy. Both pneumogastric nerves were, throughout their whole extent, minutely examined, but they presented nothing remarkable.

Exactly such is the usual result of examination after death; the patches of congestion in the stomach, and the dark colour of the fauces, and the general vascularity of every part of the body, being the only circumstances invariably found, which are, however, obviously insufficient to account for the fatal symptoms,—together with the appearance of the blood, before noticed, in which there may be material change of property. The congestion is, indeed, frequently spoken of as inflammation, but not often by those conversant with morbid anatomy, nor do the symptoms during life at all point to inflammatory action. Whether the actual appearances of the throat and stomach are not rather the effect of disease than a cause capable of exciting the irritative spasms, is very doubtful; the nerves, at any rate, going from these parts shew nothing wrong.

Very nearly similar to this is the evidence afforded by examination of the rabid dog, as I have myself repeatedly seen. This is Mr. Youatt's account of the matter, only that you must substitute congestion for inflam-

mation:—"After death, there will invariably be found more or less inflammation of the mucous coat of the stomach, sometimes confined to the rugæ, at other times in patches, generally with spots of extravasated blood, and occasionally intense, and occupying the whole of that viscus. The stomach will likewise contain some portion of indigestible matter (hair, straw, dung), and occasionally it will be distended and completely filled with an incongruous mass. The lungs will usually present appearances of inflammation, more intense in one, and generally the left lung, than in the other. Some particular points or patches will be of a deep colour, while the neighbouring portions are unaffected. The sublingual and parotid glands will invariably be found enlarged, and there will also be a certain portion of inflammation, sometimes intense, and at other times assuming only a faint blush, on the edge of the epiglottis, or in the rima glottidis, or in the angle of the larynx attached to it."

Assuming that hydrophobia is communicated from one animal to another, you would naturally expect that there would be some variety of symptoms in different species, and it seems probable *à priori* that a comparison of the disease in various genera would help us to a knowledge of its essential nature. It was from the dog that this boy had the disease, and it is from this animal that most persons derive it; and as you should be acquainted with the nature of rabies canina, and the books in your hands do not contain a very complete account of it, I will next read to you its history, as related by a most intelligent veterinary surgeon, Mr. Youatt, who has seen more of it perhaps than any other person in the kingdom.

"The symptoms of rabies in the dog are the following, and nearly in the order in which they occur. An earnest licking, or scratching, or rubbing, of some particular part; sullenness, and a disposition to hide from observation; considerable costiveness, and an occasional vomiting; an eager search for indigestible substances, as bits of thread, hair, straw, and dung; an occasional inclination to eat its own dung, and a general propensity to lap its own urine: the two last are perfectly characteristic circumstances." Symptoms these which are not present in our own species. "The dog becomes irritable; quarrels with his companions; eagerly hunts and worries the cat; mumbles the hand and foot of its master, or perhaps suddenly bites it, and then crouches and asks pardon. As the disease proceeds the eyes become red; they have a peculiar bright and fierce expression; some degree of strabismus or squinting very early appears (not the protrusion of the membrana nictitans or haw over the eye, which in distemper often gives the

appearance of squinting), but an actual distortion of the eyes; the lid of one eye is evidently more contracted than the other; twitchings occur round the eye, they gradually spread over that cheek, and finally over the whole face. In the latter stages of the disease that eye frequently assumes a dull green colour, and at length becomes a mass of ulceration." All these remarkable affections of the nerves of the eyes and the portio dura are in addition, you will observe, to what you saw in the boy. "After the second day the dog usually begins to lose a perfect control over the voluntary muscles; he catches at his food with an eager snap, as if uncertain whether he could seize it, and he often fails in the attempt. He either bolts his meat almost unchewed, or in the attempt to chew it drops it from his mouth. This want of power over the muscles of the jaw, tongue, and throat, increases, until the lower jaw becomes dependent, and is of a dark and almost black colour. The animal is able, however, by a sudden convulsive effort, to close his jaws and to inflict a severe bite.

"The dog is in incessant action; he scrapes his bed together, disposes it under him in various forms, shifts his posture every instant, starts up and eagerly gazes at some real or imaginary object; a peculiar kind of delirium comes on; he traces the fancied path of some imaginary object floating around him; he fixes his gaze instantly at some spot in the wall or partition, and suddenly plunges and snaps at it; his eyes then close, and his head droops; but the next instant he starts again into renewed activity: he is in an instant recalled from the delirium by the cries of his master, and listens attentively to his commands, but as soon as his master ceases to address him he relapses into his former mental wandering." All this is exactly like the delirium of man.

"His thirst is excessive (there is no hydrophobia in the dog), and the power over the muscles concerned in deglutition being impaired, he plunges his face into the water, up to the very eyes, and assiduously but ineffectually attempts to lap." I may observe as to this point how completely the symptom of hydrophobia generally present in the human species is vulgarly transferred to the dog; I actually remember its being stated that a London magistrate ordered a suspected dog to be taken to the pump, and there trying to drink, it was immediately turned loose again, with perfect confidence that it was not mad, after this very satisfactory test!

"His desire to do mischief depends much on his previous disposition and habits; I have known it to proceed not beyond an occasional snap, and that only when purposely irritated, but with the fighting dog the scene is often terrific. He springs to

the end of his chain; he darts with ferocity at some object which he conceives to be within his reach; he diligently tears to pieces everything around him; the carpet or rug is shaken with savage violence, the door or partition is gnawed asunder; and so eager is he in the work of destruction, and so regardless of bodily pain, that he not unfrequently breaks one of his own tushes.

"If he effects his escape, he wanders about, sometimes merely attacking those dogs which fall in his way, and at other times he diligently and perseveringly hunts out his prey; he overcomes every obstacle to effect his purpose, and unless he has been detected in the march of death, he returns in about twenty-four hours, completely exhausted, to the habitation of his master."

I am inclined to think there may be some truth in this contrast with regard to ourselves also in explanation of the difference of violence; I have seen a gentle and amiable boy quiet, and easily persuaded, and without any inclination to do mischief, and a cruel and a quarrelsome one exceedingly violent, fighting and abusing every one near him, and driving every body away; what this boy's natural disposition was I have not heard, but he was certainly at times very delirious and violent.

"He frequently utters a short and peculiar howl, which, if once heard, can rarely be forgotten; or if he barks, it is a short coarse inward sound, altogether dissimilar from his usual tone. In the latter stages of the disease a viscid saliva flows from his mouth, with which the surface of the water that may be placed before him is covered in a few minutes, and his breathing is attended with a harsh grating sound, as if impeded by the phlegm in the respiratory passages." In this also the appearance is much like what you have recently seen in the boy.

"The loss of power over the voluntary muscles extends after the third day through his whole frame, and is particularly evident in the loins; he staggers in his gait, and there is an uncertainty in all his motions, and he frequently falls, not only when he attempts to walk, but when he stands balancing himself as well as he can. On the fourth or fifth day of the disease he dies, sometimes in convulsions, but more frequently without a struggle."

In these latter symptoms is the greatest difference between the disease in the dog and in ourselves; while the earlier phenomena are the same, or nearly so, the paralysis observed in dogs is never found, I believe, in man; the muscular power is elevated rather than depressed, and that even till a late period: in this boy nearly to the last half hour. A man often exerts himself most vigorously; a patient of my brother's in the Middlesex Hospital, in alarm, jumped

over one bed after another in the ward, and was with difficulty brought back, and some restraint is generally required; the brain seems excited in man; but it is at last oppressed so as to cause palsy in the dog.

In observing this case of hydrophobia you cannot but have been struck by the resemblance that it bore in many respects to the cases of tetanus which you see so much more frequently. In both diseases a wound or injury, in which nothing particular is observed locally, is followed after a certain time by the most painful and distressing spasmodic contraction of the muscles. In both diseases there is the most exquisite irritability of the sentient surfaces, the skin, the ear, the eye, so that the touch, or even the approach of the finger, a breath of air, a noise, mental excitement, immediately causes violent spasm. In both diseases the termination is almost always fatal, in hydrophobia perhaps invariably so, and this commonly in both cases from 48 to 60 hours from the commencement of the malady, at the latest on the third, fourth, or fifth day. In neither case is there a satisfactory explanation of the symptoms, or of the cause of the patient's death, in any morbid appearance which has been observed, with sufficient constancy in any vital part to be associated with these symptoms.

And yet, notwithstanding the strong analogy between tetanus and hydrophobia, there are many points of difference. In tetanus the spasms affect the muscles supplied by the fifth nerve in all cases; in most the muscles of the trunk of the body, and in a few cases those of the extremities also; the muscles of deglutition are much affected, but many others also participate in the spasms, the whole spinal column being deranged in its actions. In hydrophobia, on the contrary, it is very seldom that any other muscles besides those of the throat are spasmodically contracted; the fifth nerve, and those of the spine, are nearly unchanged, and the eighth pair, with the phrenic nerves, seem to be chiefly influenced by the disease. In tetanus the muscles are permanently rigid, the spasm being constant with temporary increase; in hydrophobia the spasms are only occasional, and the relaxation of the muscles is perfect in the intervals. In tetanus the spinal system is much disordered, but the cerebral functions are comparatively unimpaired, and the mental powers almost always perfect to the last; delirium is hardly ever observed. In hydrophobia, on the contrary, while the voluntary muscles dependent on the spine are perfectly obedient to the will in man, and paralysed to a certain degree in the dog, the mental faculties are seriously impaired in all animals, and delirium and absolute mania are added to the spasm in almost every case. While tetanus

is not unfrequently idiopathic, occurring spontaneously, as from a chilblain, or without any apparent cause, hydrophobia never occurs, in my opinion, except from inoculation; and the same is asserted by the best observers as to the lower animals. Many cases, indeed, have been published of spasmodic affections, in which convulsions and dysphagia, and even hydrophobia, formed a prominent part, some of which ended fatally, but of which most recovered; but all these cases in my opinion want some of the essential characters of real hydrophobia, such as you saw in this boy. Whatever was its first origin, like syphilis, there is, I feel confident, no reason to believe in its spontaneous occurrence now; there is no doubt always inoculation, although some few persons think otherwise. Here, then, is the most important dissimilarity between the two diseases: traumatic tetanus may arise from any kind of injury whatever, a burn, a wound, a dislocation without any wound, a splinter inserted in a nerve or fascia, a mere laceration, a mere scratch; in hydrophobia, on the contrary, there must be inoculation from the saliva and other secretions of the mouth of a rabid animal. There is no proof, I think, that the poison resides in the saliva alone, as is usually supposed; neither is there any apparent foundation for the opinion which some have entertained, that it is contained in the secretions of the bronchial tubes; on the contrary, you saw here that the dark congestion of the fauces distinctly terminated at the glottis. It would appear quite as probable that the poison is formed in the tough viscid secretion of the fauces, which gives so much distress to the patient, those parts being invariably much altered in colour, and the glands enlarged. With this fluid of the mouth, whether mucous or salivary, or both, repeated experiments have been made, and have constantly succeeded in producing the disease in the inoculated animal. It is not necessary that a bite should be inflicted; the mere licking a part in which there is an abrasion of any kind is quite sufficient.

Let us see how this is proved as to the boy whose case we are considering. What has been ascertained with regard to this point at the inquest, or since that time, is this. The dog, which was a Spaniel belonging to the resident at the next house, was being driven by the boy out of his own house when it bit him; and it had been observed by its master to have been ill previous to this. It was then tied up, but a cat was also bitten by the dog, and a servant-girl was bitten on the thumb, and the cat's kitten was attacked and killed by the dog at the same time that it injured the boy; but it does not appear in the notes whether the servant and the cat were injured at this time or subsequently.

The dog having been tied up is then said to have fallen off in its appetite, to have had frequent catchings in the throat, and become snappish, and died about a week afterwards, according to the account the boy himself gave me, but as I have been informed by others, only five days ago. The former account would have been not unlikely if the dog died of rabies; in the latter case, though not impossible, the animal must have recovered from the usual fatal symptoms of the disorder*. It appears further that the cat was ill for some days after the bite, but soon recovered; about a fortnight afterwards, however, (and the lower animals evince the disease much earlier than ourselves,) it became stupid, and giddy, and wild, running up and down stairs, and refusing food, and while in this state scratched the boy's hand; it died three or four days afterwards, having had several fits; an account which is not unlike the symptoms of the disease in this animal. A medical man examined the stomach of the cat, and a farrier opened the dog, and both assured the owner of the dog that they died from natural causes. We have already seen, however, that such an examination is not conclusive, particularly, of course, if the dog died so recently.

Assuming, then, that inoculation is the cause of the disease in man, it is, as you are aware, most commonly produced by the dog, or other canine animal, but the cat has frequently occasioned hydrophobia in man and in other animals; and probably many other animals are capable of communicating it; experiments have been made, which make this probable of the cow; still it is rare except with the canine and feline races. Whether one human being can give hydrophobia to another has not been proved, though there seems no reason why it should not be so: we have, however, one experiment only, which is said to have succeeded; this is on the authority of Magendie and Breschet, with regard to a patient of Dupuytren's, with whose saliva a dog is said to have been made rabid, and a second dog from this, but in the third trial it failed. It has been said too that rabies is incapable of being propagated through more than three individuals of any kind; Mr. Youatt has told me, however, that he has produced the disease at least four times successively, without reference to former sources for the first dog.

Thus, then, hydrophobia is the result of an inoculated poison, but no doubt, as with all contagious diseases, a certain susceptibility is necessary in each person or other animal to make the virus act: it is thus said by Mr.

* It appears, in fact, from the evidence of the owner of the dog, that the animal really died on the Thursday following, which was April the 25th, the fourth day after he bit the boy.

Youatt that he has often known rabies come on as if from the excitement of parturition, or when the animal was at heat, when perhaps the disease might otherwise have been escaped. From this cause it is, in part, that fortunately so few persons have hydrophobia, many who are bitten by actually rabid animals not being susceptible of the poison. Many again who are bitten, and might be in a state for it, do not receive the poison, because it is wiped off by the clothes, or because several have been bitten successively. I remember an account of a physician, a Dr. Ingelhong, who was engaged in some experiments with tunicas poison, and accidentally let the knife he was using drop down upon his foot, on which he sat down, and said, "in five minutes I am a dead man." It might be curious to speculate on the state of mind of persons in this state of expectation, of which some idea may be formed from the picture given by Sir Walter Scott in *Old Mortality*. When two or three minutes elapsed, however, the Dr. thought he might as well wipe his foot, and shortly found that he was not dead, and that the poison had been arrested by the clothes.

The disease is, in fact, from these and other causes, much more rare than the public fears would lead one to imagine; I observe, for example, that, in the last report of the registrar-general (that for 1841), the total deaths in England and Wales having been 343,847, only 7 persons died of hydrophobia, of whom three died in the metropolis, two in the western district, and one in Wales; while, in the same time, no less than 118 died of tetanus. What proportion of those bitten by really rabid animals are likely to have hydrophobia I do not know; we are informed by Dr. Trollet, that out of twenty-three persons bitten by a wolf in 1817, no less than fourteen died of hydrophobia, while in many other cases only one will have the disease out of ten or twenty; for instance Dr. J. Hunter found, when twenty-one persons were bitten, that of them one only died. It seems very likely that the poison may be more virulent in one rabid animal than another, and much may depend on the mode of attack; the wolf, for instance, is said to attack the face or hands; this boy was bitten in the hand, and this and other exposed parts are more likely to be inoculated. I have been told by Mr. Youatt that he had been bitten seven times, and this not by dogs of whom many are not rabid, but by animals proved to be actually mad; and his servant had been bitten four times, but every time with impunity. I was much indebted to this gentleman some years ago for his assistance, while I was engaged in some experiments on several different remedies on rabid dogs; for it is not an agreeable task, without being perfectly con-

versant with their habits, to be putting medicines into the mouths of mad dogs.

It seems very likely that rabies abounds in certain seasons, so that in some years there are very few cases, while in others it is very prevalent: on looking at the Registrar-general's Report, which I have just alluded to, I observe that in 1838 twenty-four persons died of hydrophobia, fifteen in 1839, twelve in 1840, and only seven in 1841. Tetanus, on the other hand, not being a contagious or epidemic disease, is pretty uniform, so that there died of it, in the same years, 129, 122, 142, and 118, respectively; and the deaths altogether were more numerous in the year in which the greatest number died of this disease.

It is very probable, too, as with other epidemic diseases, that hydrophobia may have somewhat regular periods of increment and decrement, as it is termed, which makes the mortality very variable; there died, for instance, in the same years, of small pox, above 16,000, 9000, 10,000, and 6000; and of scarlatina, at first only 5000 and upwards, then 10,000, 19,000, and 14,000, in round numbers. So the hydrophobia diminished each successive year, and again perhaps will increase to a larger number.

Like all contagious diseases, hydrophobia has a certain period of incubation, as it is called, in which the poison produces no sensible effect. In this boy you found that just seven weeks elapsed from the bite till the time when the symptoms became manifest, which is a very common period; from six weeks to three months is the time in which almost all the cases of hydrophobia have been seen. I have here a table of about 130 cases of the disease, of which seventeen occurred from eighteen to thirty days after inoculation, the former date being one of the earliest periods at which a real case of hydrophobia has been observed in man: from 30 to 59 days, that is to say in the second month, no less than sixty-three took place, almost exactly half, you perceive, of the whole number; from the second to the third month twenty-three cases were seen; so that thus within the first three months five-sixths of the whole number took place; in the fourth month nine cases occurred: after this they were seen at various periods, one or two in each month, the fifth, sixth, seventh, and so on, up to the nineteenth, which was a case under Mr. Nourse's care, and is the latest time at which hydrophobia can fairly be said to have been known; there is, indeed, a case of Dr. Bardaley's, in which hydrophobia is said to have been produced by a bite twelve years before, but it appears most improbable that this was really the case.

How long the poison is latent in the wound is quite uncertain, so that precau-

tions ought to be taken in any suspected case to the last. In many cases there is observed in the cicatrix a degree of pain and heat running up the arm a day or two before the symptoms manifest themselves, but it was not the case in the present instance, nor is it by any means constant. The same uncertainty is seen in tetanus. The woman, whose thumb was bitten by the same dog as this boy, was desired by Mr. Banister to come here; but very likely she will not. Undoubtedly, in every case where it appears practicable, the wound or cicatrix should be excised; and if any doubt exists whether the whole has been taken away, caustic should be afterwards used; so should it, also, when the wounds are too numerous or extensive to have the excision performed. What caustic, however, should you employ? Theoretically, no doubt, the *kali purum* would appear more likely to destroy every part in which the poison may have insinuated itself; but it is not at all impossible that one caustic may have greater power than another of coagulating and neutralising, or decomposing, the secretion in which the poison is contained. I do not know any data on which this question can be decided, derived from a sufficient number of cases. There was a record of 106 cases of bites treated by caustic potash, by Dr. Ekstrom, who advocated the propriety of keeping the wound open for a long time, out of which one case of hydrophobia took place, because, as he alleges, the patient did not keep the wound discharging long enough; if the caustic is well applied, the sooner it heals, I should imagine, the better. Mr. Youatt told me, some years ago, that a great many persons, in consequence of his peculiar practice, applied to him after they had been bitten by dogs, and that he always used lunar caustic, which he had employed upon himself and his servant every time, and in round numbers perhaps to 400 others; and that out of this number one had died of fright, but none had had hydrophobia. This is a considerable number, of whom many must have been bitten by really mad dogs, and on the whole I am rather inclined to favour the *argenti nitras*, than the *potassa fusa*, if it can be got to every suspected part.

I have not time to describe to you the great variety of remedies which have been proposed for the prevention or cure of hydrophobia, which you will find, however, in a very good article on the subject, in Cooper's *Surgical Dictionary*, and in other works commonly in your hands. All preventive remedies must necessarily act on the principle that many would escape the disease even if nothing were done; some vegetable powders were sent to Mr. Tatum as an infallible cure for hydrophobia, of which the direction was, that as much as would lie on

a knife should be given three mornings fasting in liquid, that the patient should not eat till 12 o'clock, and that while under their use he should not have supper. A curious idea this; to talk of dinners and suppers to a person dying in forty-eight hours of hydrophobia! And all the rest are similar.

As every method had hitherto failed, out of the great number which have been employed, I determined, in the treatment of this case, to give a trial to a remedy which has been said to cure hydrophobia in India, and I believe has not yet been given in this country; and the boy took, as we have seen, as much as thirty-six grains of recent extract of the *cannabis indica* without any apparent effect whatever, unless it were some increase of the maniacal delirium, of which I am not certain; certainly without the great relief I have seen from prussic acid, or from the *milkamia guaco*, which I tried in several cases, both in the dog and in man, after some had been sent to me by Sir Robert Ker Porter, or from opium; the *scutellaria*, and other remedies, will also mitigate the disease in dogs.

But, after all, what do you gain if you remove altogether the spasms, which are so prominent a symptom during the greater part of the complaint? These spasms are only a symptom of the disorder, whatever it may be, just as they are in tetanus, indicating some obscure irritation of the nervous centres from some unknown cause. There are many hours' quiet in hydrophobia, the spasms in this case scarcely being present for more than two hours out of the last twelve, but the disease was still going on; so, also, in tetanus, I have repeatedly seen persons recover, in whom the tetanic spasms remained without remission: and I have seen them quite removed by remedies, so that a patient has said, an hour or two after the treatment has been begun, that he was in heaven to what he had been, and the spasms have almost entirely ceased, and only a little has returned just before his death; yet nevertheless he has died twenty-four hours afterwards; perhaps very nearly in the same time that he would have died if the spasms had remained.

I had at one time almost made up my mind to open the windpipe in this boy, which has been proposed by Dr. Physic, I believe, and by my former colleague, Mr. Mayo, and has received countenance from other persons also. I rather think it was done on one occasion, and that the patient died earlier than he otherwise might have done; certainly I should have run much risk if I had tried to perform it when I saw the boy in the afternoon, and found that the *cannabis* had produced no beneficial effect, for the greatest violence was produced by

my merely attempting to put my hand to him to feel the state of the larynx; he immediately began jumping up and fighting with his hands, and I am satisfied if I had shewn any instrument, or tried to open the trachea, I should have run much risk of causing instant suffocation. And after all, I am inclined to think the suggestion more plausible than likely to be generally useful; there is indeed spasm about the glottis, and it is just possible that an opening existing in the trachea, an individual both in hydrophobia and tetanus might, in some rare instance, have his life prolonged; but the cause of death is not here in almost any case of either disorder; the spasm in hydrophobia does not last long at a time, there are many intervals of rest, often many hours, and the appearances after death are not those of suffocation; the patient rather dies from failure of the heart's action; the pulse becoming exceedingly quick and feeble, gradually ceases altogether, while respiration is in many instances going on quietly and without difficulty; there is indeed general congestion of all the tissues of the body, but it is of all the capillary vessels, as it seems to me, not of the veins only, as in deaths from any species of suffocation.

We have, in fact, no principle to guide us in the treatment of hydrophobia; we do not even know the mode in which the poison acts, whether it is carried into the circulation by the absorbents, as is most probable, so as to effect a change in the whole blood, just as the poison of small-pox or syphilis does—and we have seen that the blood had a peculiar appearance to the eye—or whether, as is often supposed, it causes some mysterious effect upon the nerves of the injured part, and, through them, on the brain and nervous centres.

What it seems to me should be our endeavour is this—to make ourselves acquainted, if possible, with the earliest or preliminary symptoms; for most probably hydrophobia may always remain, as it has hitherto done, beyond our power, after the advanced stage in which alone it is now recognised has been reached. That there is such a precursory stage is certain in most instances, though they are so slight as usually to escape observation. In this boy nothing remarkable was noticed till about fifty or sixty hours before his death; but in many cases some indisposition has been complained of for a day or two beforehand; a feeling of uneasiness, chilliness, headache, weariness, or sleeplessness and restlessness, nothing more, in fact, than is often the result of derangement of the stomach and digestive organs, without fever in general; still, however, some symptoms may lurk behind which careful investigation of suspected cases months after a bite, even, may succeed in detecting, so as to lead to the discovery of a cure.

At the same time, that a cure of hydrophobia is possible, is rendered not unlikely, by the fact that rabies is sometimes cured, or recovered from, in dogs, of which there seems no doubt, from the experience of Mr. Youatt and others who have attended to the subject. So, also, it is perhaps sometimes in the human subject; at least more than one instance has been recorded in which several persons at once in the same family or neighbourhood have been bitten by the same animal, of whom one has died, and of the others some one or more have, about the same time, suffered from an indisposition—not fright—but like what I have just alluded to, from which they have recovered, and which might not have attracted notice but for the accompanying circumstances. This indisposition may have been *essentially* hydrophobia, though without coming to its usual stage. At any rate, I am convinced that in such a line of investigation alone is any cure to be anticipated.

Such then, gentlemen, are some of the reflections which this case furnishes to us, and our time allows, and, as it was to happen, I am glad that it has fallen under your notice, though I must say, as it is so frightful a disorder, I hope it will be long before you witness another of the same kind.

ON CERTAIN POINTS
IN THE
MECHANISM AND PHYSIOLOGY
OF THE
CIRCULATION OF THE BLOOD.

BY GEORGE ROBINSON,
Fellow of the Royal Medical and Chirurgical
Society, &c.

(For the *London Medical Gazette*)

SINCE the discovery of the circulation by Harvey, numerous and important functions have at different periods been assigned to it; and every year tends to add to their number. Thus, among other uses, it is generally recognized as the instrument by which nutriment is conveyed to every part of the system, and effete and noxious matters are transmitted to their proper points of discharge. But while all agree in regarding the circulation as a chief means of intercommunication and transport, there is an extensive, and highly important class of functions, in the production of which this agent is, by the majority of physiologists, considered to exert but a partial and secondary influence. The functions to which I allude all involve either the discharge through

the coats of the minute blood-vessels of certain matters previously present in the blood; or the entrance of various external substances into the mass of circulating fluid. Under the former of these divisions may be mentioned—

1st.—Nutrition, or that process by which a constant supply of their proper aliment is furnished from the blood-vessels to the different tissues of the body.

2dly.—Secretion, and excretion: and in the performance of these functions we may presume that the mechanism of *effusion* is similar, whether the matters discharged by the secreting organs are separated directly from the blood, or are matured in an intermediate series of cells.

3dly.—Under the term vascular absorption, I would comprise all those functions which consist essentially in the entrance within the blood-vessels of various external substances.

Of the forces which produce this passage of fluids into and out of the blood-vessels, and of the laws by which these forces are regulated, we know very little with certainty. The explanation at present most generally received is that advanced by Magendie, Fodera, and other French physiologists, viz. that all these functions are referable to the power of capillarity inherent in the porous coats of the vessels, and are thus analogous to the phenomena of endosmosis and exosmosis.

To this doctrine it may be objected—

1st.—That the majority of experiments adduced in its support were performed with fluids stagnant, and subjected to equal pressure—conditions which can seldom or never occur, in precisely an equal degree, to the fluids situated on either surface of the minute blood-the living body.

2dly.—This hypothesis does not explain how, in particular organs, one or other action is permitted wholly to preponderate; and it is quite certain that the two processes of imbibition and absorption do not proceed simultaneously, and with equal degrees of activity, in all the organs of the body, and in every part of the smaller sanguiferous tubes; for if an equal amount of interchange took place in the animal body wherever two fluids are separated from each other by a thin membranous septum, we should, in this case, continually incur the danger of being

poisoned by the re-absorption of excreted noxious matters.

3dly.—The same viscosity and cohesiveness, which impede so powerfully the passage of the blood through its smaller vessels, must oppose a still greater amount of resistance to that minute separation of its particles which is necessary for the effusion of albumen through the invisible pores of membrane. And the difficulty of applying this power to the explanation of certain of the functions in question is still further increased, by the fact, that in experiments with viscid fluids, they are found to imbibe much more than they exhale.

It is true that the ordinary physical properties of membrane are said to be modified in the living body by peculiar physical causes, such as heat, electricity, &c. But from a consideration of these, and other reasons that might be mentioned, it would appear that this doctrine tends to invest the porosity of membrane, considered as a cause of motion, with much greater and more varied powers than it has been experimentally proved to possess; at the same time that the functions which are referred to those powers remain as unintelligible as ever. Nor can the mechanism of these processes be fully understood, till some force more active, more manageable, and more comprehensible, than any yet advanced, is applied to the elucidation of the subject.

In the course of the following remarks I shall endeavour to demonstrate that such a force does exist in the circulation of the blood; and that this agent produces all the effects in question by directly, or indirectly, occasioning a disproportion between the amount of pressure acting on the internal and external surfaces of the minute blood-vessels. The researches on which this opinion is based were undertaken with no other object in view than the discovery of the laws by which the passage of substances into, and out of, the blood-vessels is regulated. I have at present, therefore, nothing to say concerning the means by which the different tissues and cells imbibe and assimilate their nutriment, nor of the mode in which the embryo obtains a supply of plastic matter previously to the existence of its circulation.

In these cases, the capillarity of the

investing membranes may, perhaps, in the absence of any more active force, still be considered as the chief instrument employed for this purpose.

On examining the apparatus contrived for the passage of the blood to and from the heart, we observe considerable differences to prevail in the structure of the two great systems of blood-vessels, and in the course of the currents through them.

Thus, the large arteries are thick, strong, and highly elastic, while the coats of the veins are much thinner, their structure more porous, and their elasticity less marked.

Again, the arterial blood passes from one great trunk, through several intermediate branches, into an infinite number of minute twigs; whereas, in the veins, innumerable small currents meet in more capacious vessels, by the convergence of which two or three large streams are ultimately formed.

It may further be remarked, that the arterial blood encounters numerous obstacles to its free passage into the veins; whereas, in the latter vessels, as a general rule, every facility is afforded in order to secure the free return of the vital fluid. A consideration of these and other peculiarities, therefore, naturally suggests the opinion that the two great systems of blood-vessels are in health subservient to totally distinct, if not absolutely opposite, functions; and I shall now proceed to consider the facts which bear upon this conjecture.

PART I.—*Of the uses served in the animal economy by the various impediments which the blood encounters during its passage from the ventricles into the veins.*

The existence of numerous impediments to the free passage of the arterial blood is a fact so generally known and acknowledged, as to render unnecessary any thing more than a brief mention of some of the most important obstructing causes.

The first to be considered is the arborescent arrangement of the arteries; which not only increases the surface of the vessels, and thus augments the friction, but also implies the division of the main current into as many minute streams as there are arterial twigs. The impediment arising from this cause must be materially augmented by the great viscosity of the

blood; for the cohesion existing between its particles will oppose a considerable resistance to their necessary separation from each other.

2dly.—We have the obstacles to the flow of blood occasioned by gravity—the weight of adjacent parts—the friction consequent on the angular origin and tortuous course of the arterial branches—muscular contraction—the resistance of the blood previously contained in the vessels, and some of minor importance.

3dly.—The arterial blood, before entering the capillaries, has to encounter the impediment to its passage caused by the contractility of the smaller arteries and capillaries. In mentioning this vital property of the minute vessels as a chief obstacle to the progress of the arterial blood, I would beg to remark—1st, that our estimate of the aggregate amount of resistance opposite to the blood's passage through the small arteries is to be drawn from an examination of that encountered by the separate streams; and not from a vague calculation as to the relative areas of the aorta, and of its terminal branches; and 2dly, that as the contractility of the small arteries and capillaries can, during its action, only cause a diminution in the area of the tubes which they form, and as that power of contraction is more marked in the distal part of the arterial twigs than at their point of origin from the main branch, it should follow that each minute stream of arterial blood will, if there be any difference in this respect, rather flow from the wider to the narrow portion of the tube.

Now the existence of these obstacles being undoubted, and their sum being so very considerable, are we to regard them as defects in the constitution of the circulation—unavoidable perhaps, but nevertheless involving a certain loss of power which might otherwise have been usefully employed in propelling the blood? And if the mere passage of that fluid through its vessels be deemed the sole intelligible part of the circulation, if we are to forbear from inquiring in what manner it produces its known beneficial effects upon the system, I do not see how some such supposition is to be avoided. But since it is possible that these very impediments to the circulation may in reality be contrivances adapted to the perform-

ance, by it, of some important functions, we are, I think, required, were it but in acknowledgment of the universal wisdom of nature's plans, to pause, before we pronounce these apparent imperfections altogether inoperative, or disadvantageous. It therefore remains for us to inquire whether any peculiarity in the physical condition of the arterial blood is induced by the existence of these obstructing causes. And supposing this question to be answered in the affirmative, it will still remain to determine how far that physical condition of this portion of the vital fluid is subservient to any physiological uses.

The first effect resulting from the peculiar form, arrangement, and vital properties of the arteries, is a diminished rate of discharge of blood from the minute arterial ramifications into the capillaries and veins. And this is a necessary consequence of the established laws of hydraulics. For as any impediment to the passage of a fluid along its containing tube is known to diminish the rate of discharge from that tube, so, in like manner, must the impediments to the passage of blood through the small arteries cause the quantity of fluid leaving those vessels in a given time to be much less than what would escape from them in the same time, supposing those obstacles not to exist.

The only objection which strikes me as likely to be urged in opposition to this view is that embraced in the old opinion, that the arterial blood flows from the narrow to the wide portion of a conical tube, in consequence of the aggregate area of the minute arteries being greater than that of the aorta. But even if this statement were correct—though its truth has certainly not been satisfactorily demonstrated—it is nevertheless quite clear, that the obstacle to the blood's passage occasioned by the minute subdivision of the main current of viscid fluid, will more than counterbalance any advantage which might otherwise have been derived from the jointly increased calibre of the smaller arteries. So that the practical result, viz. the rate of discharge of blood from those vessels, will, as before stated, be precisely similar to what would be obtained were the arterial blood really to flow from the wide to the contracted portion of a tube.

The arrangement of the system of

arterial tubes is therefore such as to present greater facilities for the entrance of blood, at one end, from the heart into the aorta, than for its discharge at the other, from the small arteries and capillaries into the veins.

And consequently, if the ventricle invariably expelled the whole of its contents at each contraction, there would, during an excited action of the heart, be so great a disproportion between the rates of influx and efflux of the arterial blood, as to render a rupture of some of the containing vessels almost inevitable. But it appears to me that this evil is to a certain extent guarded against by the following simple provision—viz. that the opposition to the entrance of fresh fluid from the left ventricle into the aorta increases in a direct ratio to the amount of disproportion between the rates of influx and efflux of the arterial blood. This opposition to the flow of blood from the heart arises from the backward pressure of the mass of aortic blood, which after distending the arterial walls is by their reaction driven back upon the aortic orifice of the ventricle. And as the extent to which the aortic walls are distended is, *cæteris paribus*, proportioned to the quantity of blood detained in it at the time, and as the quantity of this blood is again wholly dependent upon the preponderance of the influx over the efflux of arterial blood, so it follows that whatever increases the disproportion between the rates of influx and efflux of that blood will at the same time add to its backward pressure, and thus impede the flow of fresh blood from the ventricle.

The condition which, in a healthy state of the body, regulates the efflux of blood from the arterial system, is evidently the contractility of the small arteries and capillaries—a force influenced by the nervous system, and known to be of varying activity;—while the influx of blood is still more distinctly referable to the contractions of the ventricle.

Now if this cavity of the heart invariably emptied itself at each stroke, we might readily estimate the rate of influx of the arterial blood by ascertaining the number of its pulsations; but, from the previous reasoning, it appears more probable that the ventricle does not always expel the whole of its contents at each contraction, and

that the extent to which it does so, at any one time, mainly depends upon the relative quantity of blood then contained within the aorta: for when the quantity of this detained blood, and the consequent distension of the aorta, are very much diminished, as after loss of blood, then the opposition to the influx of fresh fluid from the ventricle is so much reduced, that it may readily empty its contents into the aorta; but if the heart's action be suddenly increased at a time when the quantity of blood detained in the aorta is already very considerable, each contraction will but add to the resistance opposing the entrance of fresh fluid into the arterial system, and will thus prevent the ventricle from expelling the whole of its contents at each pulsation.

As the causes impeding the flow of blood through the arteries exist throughout the whole extent of that system of tubes, increasing in their amount of opposition until it reaches a maximum in the minute vessels immediately continuous with the veins, it follows that the act of accumulation or detention of a quantity of blood behind each impeding surface will also continue in operation from the origin of the aorta to a point corresponding with the most contracted portion of the capillaries.

The blood thus detained in the arterial system, being prevented from moving readily forwards by the impediments so often referred to, while it at the same time receives an onward impulse from each successive wave of blood which leaves the ventricle, must necessarily exist in a state of compression, and will, consequently, exert a certain amount of outward or lateral pressure. If the obstruction to the blood's passage through the arteries were complete, then the accumulated fluid would of course be stagnant, and, like all other stagnant fluids, would transmit the whole of the impelling pressure equally in all directions. But as the obstacles occurring in the arteries present only a partial obstruction to the blood's passage through those vessels, the distending force of the arterial blood cannot be estimated till we have previously determined in what proportion the lateral pressure of a fluid is increased by the existence of any impediment to its free discharge from the containing tube. The fol-

lowing experiments, though rude and not sufficiently extended for the finer purposes of physics, may perhaps enable us to form some idea of the rate of increase in the lateral pressure of a fluid under these circumstances.

EXP. I.—I took a small wooden vessel, holding about three gallons of water, and fitted, horizontally, to its lower part, a cylindrical tin pipe, three inches long and half an inch in diameter (fig. 1). On the upper surface of this

FIG. 1.

- a. The reservoir.
- b. The horizontal pipe communicating through the minute apertures, c. c. with the interior of the vertical glass tube, d.
- e. e. The external orifice of the horizontal pipe, of its full diameter.
- f. f. The same reduced in diameter from $\frac{1}{4}$ to $\frac{1}{8}$ of an inch.
- g. g. The same still further reduced to $\frac{1}{16}$ th of an inch.
- h. The height to which the water rose in the glass tube when the diameter of the external orifice was reduced to f. f.
- i. Its height at the time that the external orifice was contracted to g. g.

pipe, ten small holes, each about one-twelfth of an inch in diameter, were made at an equal distance from each other, so as to extend along the whole length of the pipe, with the exception of half an inch at either end: over these apertures an arched piece of tin was soldered, from the centre of which projected upwards a short branch, and into it was fitted, vertically, a glass tube, twenty inches long and one quarter of an inch in diameter. The junction of this tube with the short vertical branch was made water-tight, and the descent of the former into the main passage, through the tin pipe, was of course rendered impossible by the minuteness of the communicating apertures. The wooden vessel or reservoir was then filled with water to a height of twelve inches above the entrance of the tin pipe, and the column in it was maintained at the same elevation by the constant addition of fresh

fluid. On removing a plug which had been previously placed at the inner orifice of the tin pipe, the water rushed through the latter, and escaped in a jet, sweeping, in this course, across the minute apertures which communicated with the interior of the glass tube.

During the whole of the time that this flow continued, there was no ascent of water in the glass tube; shewing that, if the stream traversing the tin pipe did exert any lateral pressure, its amount was so inconsiderable as to be incapable of raising a column of water to the height of one inch; for it would then have been perceptible in the tube.

EXP. II.—The apparatus being in every other respect untouched, a short straight tube, one-third of an inch in diameter, was so fastened into the centre of the outer orifice of the tin pipe as entirely to prevent any escape of fluid from the latter, with the exception of that which passed through this smaller tube. The height of the column maintained in the reservoir was the same as in the last experiment, viz. twelve inches. On then allowing the water to enter the tin pipe, and escape freely through its narrowed extremity, it instantly rose in the vertical glass tube to a height of nine inches, and continued at that elevation as long as the same column of water was maintained in the reservoir. On allowing the latter to fall to ten inches, the same proportion was still observed between its height, and that of the fluid in the glass tube, which had, during the same time, fallen to seven and a half inches.

EXP. III.—Every other condition being precisely similar, the tube one-third of an inch wide was withdrawn from the outer orifice of the tin pipe; and replaced by one one-sixth of an inch in diameter. On the re-admission of water into the tin pipe, it instantly rose in the glass tube to within half an inch of the height of the column in the reservoir, viz. to eleven and a half inches, though a jet one-sixth of an inch in diameter was, at the same time, escaping through the outer orifice of the horizontal pipe. A finger was now placed upon the inner orifice of this pipe, where it projected into the reservoir, and slowly drawn over it, so as gradually to diminish the area of the stream of water entering it; and it was observed that, in proportion as that diminution took place, there was a

corresponding fall of the fluid in the glass tube, till, with a certain extent of closure of the inner orifice, there ceased to be any ascent of water in the vertical tube.

When the column in the reservoir was allowed to fall, the same proportion between its height and that of the water in the glass tube was still preserved, the difference never exceeding half an inch.

In these experiments it was very evident that the amount of lateral pressure exerted by the water traversing the horizontal pipe, as measured by the height of the column in the glass tube, was altogether dependent on the degree of facility afforded to the passage of the fluid through that pipe, by the relative areas of its inner and outer orifices.

While the conditions affecting the influx and efflux were equal, the lateral pressure was very inconsiderable; but when the discharge was diminished by the application of an impediment to the outer orifice alone, then the lateral pressure increased in a very rapid ratio. Thus, in the second experiment, a diminution in the diameter of the outer orifice, from one-half to one-third of an inch, increased the lateral pressure of the contained fluid from something less than a column of water one inch in height to that of one nine inches high, which was equal to three-fourths of the whole impelling force; and in the last experiment, a diminution of the diameter of the external orifice to one-third, viz. from one-half to one-sixth of an inch, caused the lateral pressure of the fluid in the horizontal pipe to approach to within half an inch of that of the impelling column.

Before applying these principles to the fluid contained in the arteries, I may be allowed to repeat a former observation, viz. that whatever proportion the area of the aorta may bear to that of the sum of its terminal branches, the obstacles preventing the free passage of blood through the latter will diminish its rate of discharge from them as virtually as though their joint calibre were actually less than that of the main trunk; and as the amount of lateral pressure exerted by a moving fluid is wholly regulated by the relative facilities afforded to its passage into, and out of, the containing tube, so the various obstacles opposing the free

course and discharge of the arterial blood will increase the lateral pressure of that fluid as effectually as the diminution of the external orifice of the pipe did in the foregoing experiments. The truth of this latter statement may also be proved by actual experiment.

Exp. IV.—Thus, having connected with the same reservoir a leaden pipe, a yard long, perfectly straight, of uniform calibre, and maintained in the horizontal position, I bored a small hole on its upper surface, at the distance of a few inches from its commencement. A full stream being then allowed to flow through it, there was no escape of water from this aperture, shewing that the lateral pressure exerted by the moving fluid was at a minimum. I now bent, laterally, the external half of the pipe, so as to cause it to describe a gradual curve, the horizontal position being still carefully preserved, and its calibre being apparently unaffected. But when the stream was again permitted to traverse it, the lateral pressure of the fluid detained behind the curve had increased so much as now to cause a small jet to escape through the aperture.

It is therefore evident that, in addition to contraction, any of those other peculiarities in the form and arrangement of tubes, which are known to diminish their power of discharge, will also increase the lateral pressure of the fluid contained behind the impeding portions of the tube; and as it has, moreover, been shewn that the amount of lateral pressure increases in a very rapid ratio on the application of any impediment to the free discharge of fluid from a tube, so it is rendered probable that the outward or distending pressure of the arterial blood is very considerable.

A question here arises as to the proportion which this lateral pressure of the arterial blood bears to the impelling power of the heart. The data which we possess may perhaps be deemed insufficient to warrant a positive answer, but, for the following reasons, I should imagine that these forces must generally be very nearly equal. The onward impulse of the arterial blood is supposed, from experiments performed on animals with the hæmodynamometer, to be equal, in man, to a column of the same fluid eight feet

high. Poiseuille has, moreover, found this impulse to be nearly equal in the chief arterial branches. Now it follows, from the arborescent arrangement of this system of tubes, that the force of the blood entering the carotid artery must be nearly the measure of the lateral pressure of the aortic blood; and as the impulse of the blood entering the femoral artery, which, in direction, is continuous with the aorta, is no greater than that of the blood driven into the carotid, which is a lateral branch, it would appear that the mass of aortic blood presses equally in all directions, its lateral being equal to its onward pressure*. And, from the facts and arguments before mentioned, it is equally evident that this great lateral pressure of the fluid contained in the arteries can only be occasioned by the existence of a considerable difference between the relative facilities afforded for the influx and efflux of the arterial blood. As to the absolute force of the onward pressure, it must necessarily be subject to a still more extensive range of variation than that of the onward impulse derived from the heart's action; for it is equally affected by a change in the condition of the heart, or of the smaller vessels, both which changes are continually occurring. It may therefore, in the same individual, be at one time so slight as to be incapable of accomplishing its healthy uses, while, at another period, its distending power may be so considerable as to rupture some of the containing vessels, and thus threaten the destruction of life.

Having, I trust, satisfactorily proved that the whole mass of arterial blood exerts, during health, a considerable amount of outward or distending pressure, it now only remains for me to consider the second point which I proposed for examination, viz. whether any uses are served in the animal economy by the existence of this peculiar physical condition of the arterial blood; and, in studying the physiological effects resulting from the operation of this force, it will be necessary to view it as existing, first, in the large arteries, and, secondly, in the minute arterial ramifications; for as the phy-

sical and vital properties of these vessels are essentially different, so will the application of the same distending force produce, in each, totally distinct phenomena.

The coats of the large arteries being dense, thick, and highly distensible, it is evident that an accumulation of blood in, and a forcible distension of, those elastic tubes, are the only effects which *can* occur from the detention within them of a quantity of highly compressed blood; for the escape of any portion of the contained fluid through the pores of the investing tissues is prevented by the great thickness and dense structure of the arterial tunics. It is also quite clear that any considerable accumulation of fluid can only take place in a tube when the walls of that tube are either flaccid or elastic; and that, in the latter case, the amount of the accumulation will, to a certain extent, be regulated by the distending power of the contained fluid. Since, therefore, various functions have been traced to the reaction of the elastic coats of the large arteries upon the distending force of the blood accumulated within them, and since that distending force has been shewn to be no other than the lateral pressure of the arterial blood, we are, I conceive, now authorized to advance a step further, and say, that the functions in question are referrible to that lateral pressure as to the cause essentially producing them. The uses to which I more particularly allude are the equal distribution of the heart's impulse throughout the system, and the uniform and equable flow of blood through the capillaries and veins.
